Owing to the great variation in the resistance of organisms under different conditions, it is always necessary to try out calculated processes with the organisms present in the actual food and to note their adequacy under actual practical conditions. In this way something very closely approaching complete sterility can be readily achieved, but as foods must have other qualities besides sterility to recommend them, the problems in practice are considerably less simple.

The practicability of calculated processes.—Too prolonged heating destroys the characteristic taste and appearance of many foods, and the crucial problem in food preservation is to devise that process of heating which will eliminate troubles of bacterial origin, without impairing the appearance and flavour of the food.

It has been shown that in the case of highly resistant spores the rate of destruction increases very rapidly with the temperature after a given minimum, *e.g.*, for *B. botulinus*, heating for 6 min. at 115° C. may be as effective as for 60 min. at 105° C.

It is found in practice that the taste and appearance of foodstuffs are less affected by a short cooking at a higher temperature than by a slow cooking at a lower temperature. This suggests the adoption of processes at a high temperature for a short time, *e.g.*, under certain conditions a process of 115° C. at 20 min. has the same sterilising value relative to the sporing aerobes described as a process of 107° C. for 65 min.

The treatment of food previous to the sterilisation process is also a matter of importance here, and the methods employed in packing foods may be briefly considered.

The container materials used are tin-plate and glass. Containers made of tin-plate may be sealed by either the solder or the double seam method; in either case the can is first exhausted of air by heating, so that there will be a low internal pressure in the sealed, cooled can. This step is largely necessitated by the much increased chemical action which takes place between the food and the tin-plate in the presence of oxygen. Glass containers may be sealed by the Phœnix cap, as already described, which leaves a layer of air above the food, or by one of two methods which remove the air, so that ultimately the cap is kept in place by the external atmospheric pressure.

In one of these methods—that of the automatic cap—the jars are heated slowly with the cap held in place by steel bands. This drives out the air and produces the desired low internal pressure. Here sterilisation must be carried out in an open water-bath.

A new method has recently been introduced in which the air is removed from the jar mechanically with the lids held in place. External pressure again keeps on the caps after the vacuum is released in the exhausting machine. This type of container is sterilised in a special retort into which compressed air can be introduced. The heating is effected by steam under pressure, but the pressure outside the jars is maintained at a higher level than that inside, by admitting compressed air into the retort.

Thus in three of the methods in common use the food is inevitably slightly cooked before the actual sterilising process begins. Some types of food must also be heated to facilitate the mixing of ingredients or to allow the foods to be packed in certain shapes of containers. It has been found that where the initial temperature of the food is increased the sterilising process may be decreased by varying amounts depending on the type of food and container, and on the temperature of the process.

It is therefore necessary in some cases where this preliminary heating takes place to arrange that the sterilising process shall follow before considerable cooling can take place. This assists in effecting adequate sterilisation without over-cooking.

The effect of this heating on the vitamins of the food cannot be overlooked, but recent work has shown that much of the destruction originally attributed by workers in this field of research to heat is really due to oxidation. This points to the desirability of developing those methods of packing and sterilising preserved foods in which no considerable heat is applied until the partial pressure

of oxygen in the container has been reduced. Tests on some canned vegetables heated only in this way have shown that they have retained much more of their vitamins than the same vegetables cooked in the usual way for domestic consumption.

The most important factor in determining whether a food can be given a perfectly safe processing is undoubtedly the size of the container. The outer layers of a food package must always receive a much greater cooking than the inner. There is therefore clearly a practical limit to the size of the container which can be used. The shape of the container has, however, a considerable hearing here. Values for the time required for the centre of the food to reach a given temperature have been calculated on the assumption that convection currents were entirely eliminated, and these have shown that the ratio of the length of the container to the diameter is an important factor in determining this time.

Actual experiments have shown that, with certain foods, if the nett volume of a container be doubled with the height approximately constant, the process time necessary for sterilisation must be more than doubled, whilst for a container of the same volume but different shape (a reduced ratio of length to diameter) the time is only increased by about 50%.

In America the size and shape of containers are legally standardised: if such a course were ever contemplated in England the bearing of these on the sterilisation of the foods would appear to be a matter for consideration.

Discussions have taken place recently as to the relative merits of tin-plate and glass as containers, with special reference to the heating necessary for sterilisation, and various public health experts have expressed preference for tin-plate. In actual practice, however, there are many factors operative to make glass ultimately the more satisfactory.

(1) A good grade of glass is necessary even for the partial sterilisation essential for the production of those "keeping qualities" which are the *sine qua non* of any type of preserved food.

(2) When the heating has been carefully planned to give the best effects not only for sterility but also for taste, the glass normally used for containers presents no difficulties in the way of sterilisation.

(3) Chemical reaction between the glass and the food is negligible, whilst such reaction in the case of tin-plate always occurs to a greater or less extent.

(4) All faulty glass packages are weeded out in the heating, so that spoilage on the market due to leaking glass packages is almost unknown, whilst it has been shown that a very large proportion of the spoilage of canned goods is due to small leaks which either admit the organisms responsible for the spoilage, or admit air which enables organisms already there to develop.

The size and shape rather than the material of the container would, therefore, seem to be the factors of fundamental importance in devising satisfactory sterilising processes.

Retort control.—This having been done, it remains to ensure that these processes shall be actually carried out under factory conditions. A temperature recorder for each retort gives a written record of the internal temperatures. By a very simple method any considerable variation in this temperature in different parts of the retort may be noted and considerable information as to the actual heating of the foodstuffs may be gained. It has been seen that heating to a high temperature for a short time can have the same sterilising value as heating at a lower temperature for a much longer time, with much less danger of over-cooking. It thus frequently happens that the process used is one in which the centre of the pot only just reaches the temperature of the retort or never reaches it at all. If, therefore, a small maximum thermometer is placed with its bulb in the centre of a pot which is processed, it will register the temperature there at the end of the process, because the maximum is only reached at the end. If this temperature is that deduced from heat penetration studies under the given conditions, then the food must have been heated at least as efficiently as is desired.

Tests of this kind have been made on a large number of samples placed in different parts of different retorts and have shown a very high degree of agreement with each other and with the temperature theoretically expected. There seems, therefore, no reason to suppose that the temperature in any part of the retort differs from that registered by the thermographs.

It has been seen that in preserving food there exist many variable factors influencing the sterilising value of given retort processes, some of them peculiar to the bacteria themselves, others dependent on external conditions such as the rate of carrying through certain operations.

It might appear, therefore, that very consistent results could not be obtained, as it might always be possible that an organism slightly more resistant than those examined might be found.

Safety factors in practical application.—There are, however, certain safety factors which allow for a considerable margin of variation in practice. The resistances of bacteria, as has been pointed out, are frequently expressed in terms of the temperature of the oil-bath and not of the organisms themselves. If the bacteria could actually be raised instantaneously to that temperature this resistance would clearly seem less. But the temperature of the centre of the pot used for the calculation of the process time refers to the actual temperature of the food, and therefore of the organisms. In the case of the higher temperatures this factor may be of very great importance.

Secondly, all organisms not placed exactly in the centre of the jar receive more, and in some cases very much more, than the minimum heating required to kill resistant forms.

As a result of their investigations of the bacterial condition of canned meat and fish, Savage[3] and his co-workers came to the conclusion that the successful exclusion of air from the contents of cans was of greater importance than the sterilising processes usually given, because of the incompleteness of those processes.

In his book on botulism, Leighton§ points out, however, that for safety an efficient final sterilising process is absolutely essential, but questions whether this is practicable for all foods. This is not a question to which a conclusive answer can yet be given, but it would seem probable that by suitable choice of shape and size of container and careful adjustment of all preliminary heating operations an adequate sterilising process may be given to any type of food, while preserving the essential characteristics of the food.

[illegible] I desire to thank Messrs. Angus [illegible] subject, for permission to include some of the [illegible] to require [illegible].

THE PREPARATION OF ETHYL ETHER BY WILLIAMSON'S METHOD.

BY W. B. S. BISHOP, B.SC.

The preparation of ethyl ether by Williamson's method from ethyl iodide and sodium ethoxide was originally undertaken with the object of testing whether pure ether made by this method possesses anæsthetic properties. At the time when the work was started, ethyl ether prepared synthetically had not been tested as an anæsthetic, but in 1922 experiments were published by Stehle and Bourne* in which ether prepared from ethyl iodide and sodium ethoxide was used, the results showing that ether so made was as good an anæsthetic as the ordinary anæsthetic ether. Stehle and Bourne give no details of their method of preparation, but state that their ether contained a little ethyl iodide.

That pure ether is an anæsthetic has been definitely proved by the experiments of Dale, Hadfield, and King.† The ether used in their experiments was made from alcohol and sulphuric acid.

The literature contains practically no details of the preparation of ether by the synthetic method, the only reference being to Williamson's original paper.‡ Preliminary experiments showed that ethyl chloride was somewhat troublesome to use, and did not give good results. Ethyl bromide was found unsuitable, as it was impossible to free the ether from the last traces of bromide.

Ethyl iodide was therefore adopted as the most suitable halide. Preliminary experiments showed that it was somewhat difficult to separate the ethyl iodide from the ether itself. Excess of sodium oxide was therefore used in order to react with as much of the ethyl iodide as possible.

Ethyl iodide.—The older methods of preparation nearly all involve the use of yellow phosphorus, the main advantage of this over red phosphorus being that the reaction proceeds faster, and may be made automatic by the use of special apparatus.§ This method appears to be most convenient for large quantities of ethyl iodide (about 4–6 kg.) and gives very good yields. In the present work however, relatively small quantities of ethyl iodide were required, and the method adopted was that of E. Hunt.* The only departure from that method was that the amounts of the reacting substances were doubled, the resulting yield being slightly greater (by 2%) than that given by Hunt.

Experimental.

Iodine (1221 g.) was mixed with 80% ethyl alcohol (450 g.) in a 3-litre flask, the mixture was cooled, and 90 g. of red phosphorus (an excess) added during twenty minutes. The reaction was so controlled that no iodine vapour escaped. The mixture was heated under a reflux condenser for three hours on a boiling water bath and then distilled, the fraction from 63° to 83° C. being collected. The distillate was colourless, whereas that from a former preparation using yellow phosphorus was discoloured with iodine. The distillate was washed with a dilute solution of sodium carbonate containing a trace of sodium thiosulphate, dried over calcium chloride, and distilled, the fraction of b.p. 72·3°–72·4° being collected. This fraction was free from alcohol. The yield of pure ethyl iodide was 1425 g. (95% theory on the iodine used; Hunt obtained 92%). From the quantity of phosphorus recovered (28 g.) it appears that the reaction proceeds according to the equation given by Beilstein and Rieth† and noted by Hunt (*loc. cit.*), *viz.*:—

$$P+5I+5C_2H_5OH=5C_2H_5I+H_3PO_4+H_2O$$

and not according to that usually given in textbooks, *viz.*:—

$$P+3I+3C_2H_5OH=3C_2H_5I+H_3PO_3.$$

For converting the ethyl iodide into ether a solution of sodium oxide in absolute alcohol was used. In the subsequent experiments a large excess of ethyl alcohol was used to prevent the separation of ethoxide from solution. To remove the last traces of the petroleum from the sodium, each piece, after drying on filter paper, was dipped in absolute alcohol, and then used in the preparation of the ethoxide.

To 2 litres of absolute alcohol in a 3-litre flask, cooled by running water, 187 g. of clean metallic sodium was added in small pieces at a time. The solution showed no signs of darkening, as is observed in the solid substance, but remained quite clear. This solution represents 552 g. of sodium oxide in 1215 g. of absolute ethyl alcohol.

Ethyl ether.—The ethyl iodide (1265 g.) was added gradually to the solution of sodium ethoxide (552 g.) in a 4-litre flask, fitted with a 12-bulb pear still-head and thermometer, attached to a bulb condenser (Allihn's) through which ice-cold water was circulating. The ether was collected in a Dewar flask, whereby the loss due to evaporation was reduced to 3%. An excess of sodium ethoxide was used to prevent any of the ethyl iodide being subsequently distilled unchanged. The iodide was added at the

† Annalen 1863, 126, 250.

same rate as the ether distilled, by means of a dropping funnel reaching to the bottom of the flask. The reaction did not commence until 100 g. of the ethyl iodide had been added, and then it proceeded violently unless checked by cooling. If, however, the sodium ethoxide was warmed to 60°–70° C. and the iodide then added, the reaction began at once. After most of the iodide had been added and the ether bubbles were no longer visible in the mixture, it was found necessary to heat the mixture to drive off the ether, but the thermometer in the still-head did not rise above 45° C. This fraction was collected separately and was found to contain a trace of ethyl iodide, which was removed by twice distilling with solid sodium ethoxide. The yield of crude ether containing alcohol was 540 g.

The crude ether distillate (30°–45°) was dried over solid potassium hydroxide for one week, and then allowed to stand over a mixture of solid potassium hydroxide and potassium permanganate (2 g. of each per 100 c.c. of ether) for two weeks, being shaken occasionally, and then distilled. The fraction 34°–35° C. was allowed to stand over metallic sodium for one week, decanted, and distilled through a 12-bulb pear still-head, the fraction 34·45°–34·5° at 760 mm. being collected. The b.p. agrees exactly with that given by Wade and Finnemore.* The yield of pure dry ether (b.p. 34·45°–34·5°, $d^{15.5}$ 0·7199(8), n_D^{15} = 1·35543) was 480 g., or 80% of theory on the ethyl iodide used. The ether gave negative tests for water, aldehydes, alcohol, halogens, and acids.

The products recovered were:—alcohol 1360 c.c. ($d^{15.5}$ 0·819), *i.e.*, approximately 90% of the excess alcohol used for the solution of the sodium oxide; phosphorus 28 g. (93% of that used in excess of theory); sodium iodide 105·6 g. (88% of theory).

For the preparation of 1 kg. of ether by the method given in this paper, with a yield of 80%, the following quantities are required:—Metallic sodium, 390 g.; iodine, 2·4 kg.; red phosphorus, 140 g., absolute ethyl alcohol, 3 litres; ethyl alcohol 80%, 1·02 litres.

* Chem. Soc. Trans., 1909, **95**, 1842.

Detection of halogens.—A method commonly employed as a test for halogens in organic substances is to dip a piece of well-oxidised copper gauze into the liquid, and then place the gauze in a Bunsen flame, which becomes green if a halogen be present. This test was found to be more delicate than Lassaign's test (dropping into sodium vapour, adding excess of nitric acid and then silver nitrate) even if benzaldehyde were used as a solvent. Burning the ether in a lamp as recommended by Rübke,* using benzaldehyde as a solvent, failed to detect less than 0·05% of the halogen u[illegible] of th[illegible]c. of ether. With the copper gauze it therefore, a[illegible] detect 0·05% of ethyl iodide in [illegible]ced with its [illegible] of iodine. The gauze used absorbed [illegible]ccessed, it [illegible] the ether at one dip, so that the amount of i[illegible] actually detected is 0·00004 g. It was also f[illegible] possible to detect 0·01% of bromine in the e[illegible] The delicacy of the test for chlorine was [illegible] determined.

Summary.

(1) Pure ether can readily be produced [illegible] Williamson's synthesis, using ethyl iodide [illegible] sodium ethoxide, with a yield of 80% of [illegible] theoretical amount, calculated on the ethyl iodid[illegible]

(2) The copper oxide test for halogen compo[illegible] in ether will readily detect 0·00004 g. of io[illegible] present as ethyl iodide.

In conclusion, I have to express my thank[illegible] Professor J. A. Schofield, for suggesting the w[illegible] and for his help in the preparation of this pape[illegible]

TRANSACTIONS

Vol. XLIII., No. 6.] [February 8, 1924.

FURTHER NOTES ON THE CONSISTENCY OF ROAD TARS.

BY D. C. BROOME.

In a previous communication by the author on ve subject,* several facts were noted which d to require further investigation, and the paper is an account of some experiments ve been carried out in order to throw further n three of these problems, namely the effect consistency of a prepared tar of :—

he addition of powdered fillers.

he addition of bitumens.

The maintenance of tar at an elevated temerature for long periods.

The addition of fillers.

as previously stated that experiments have that granite-dust, limestone-dust, and cement e an identical effect on the consistency of tar. , however, been found that if limestone-dust d as a filler in granite tar-macadam the actual s obtained are better than if granite-dust e only filler. The two facts are difficult to cile with each other, and further investigation undertaken to discover an explanation for uperiority of limestone-dust shown in practice. ne "affinity" of limestone for tar is a property hich, so far as the author is aware, has not been ıvestigated to any great extent; but many roadıakers contend that there is something in the ature of limestone that renders it exceptionally ıitable for use in tar-macadam. Some suggest ıat the reason is the ease with which limestone is ushed under the roller, the road being thus more adily consolidated; but all limestones do not ush to an appreciable extent. For example, the mestone of Emborough, Somerset, is harder than any other road stones that do not give such tisfactory results. The only suggestion put forward explain this is that limestone possesses some operty that is not altogether understood, but which s been termed "affinity."

The author has found that the apparent similarity ove mentioned between limestone and graniteıst is only temporary. In other words, if a mixture tar and limestone-dust is prepared and tested mediately the consistency of the mixture is found be normal, *i.e.*, agreeing with the equation $V_F = V^x$ ere V is the consistency of the original tar and V_F at of the mixture of tar and limestone-dust at e same temperature. If tested again later, the sistency is found to have increased, and it inues to increase until at last a maximum is ained in a time varying considerably according to the conditions of experiment; from this point the consistency remains constant. This increase in consistency is such that the final consistency (V_L) is given approximately by the equation $V_L = V^{x^2}$. The reinforcing effect taking place after mixing is, therefore, $V^{x^2} - V^x$. In the case of the other fillers, no increase in consistency apart from the initial increase could be detected.

The following table gives some consistency figures obtained with various mixtures of tar and limestone-dust and clearly shows the gradual reinforcing effect referred to.

TABLE I.

Original tar.		Hours after mixing. Nil.	3.	6.	24.	48		V^{x^2}
11	..	13	14	14	15	15	..	14
36	..	44	47	48	50	50	..	49
40	..	48	50	51	54	54	..	55
45	..	52	54	56	60	60	..	62
48	..	55	60	63	69	69	..	67
50	..	60	64	66	68	68	..	70
57	..	66	71	74	81	81	..	80
60	..	69	75	79	85	85	..	85
65	..	72	80	85	93	93	..	93
90	..	105	110	115	125	125	..	132
100	..	120	130	135	160	160	..	148
195	..	245	290	310	340	340	..	306

This gradual reinforcing effect has obviously some connexion with the superiority of limestone-dust shown in practice and is doubtless due to the "affinity" of limestone for tar, but it is difficult to find a satisfactory scientific explanation of this. The following have been suggested as possible explanations :—

(*a*) Chemical reaction between the limestone and some constituent or constituents of the tar.

(*b*) Absorption—the less viscous constituents of the tar being soaked up by the stone, the effect being as though they were removed altogether from the mixture.

(*c*) Adsorption — a molecular surface reaction between the limestone and certain constituents of the tar.

Of these suggestions the first may be rejected as unlikely (though not definitely impossible) as no evidence of any such reactions can be found. Similarly, the second suggestion is without foundation; and further, the author's experiments are evidence against the validity of this suggestion, for it is noted above that the percentage increase in consistency is higher with tars of high consistency than with those of low consistency, whereas the presence of a higher percentage of light oils in the latter would give greater facilities for absorption if this took place. The author therefore puts forward the third of the above suggestions as the one which best fits in with the facts. It should, however, be noted that this is only a suggestion, as the present state of the experimental evidence is not sufficient to allow a definite conclusion to be drawn.

J., 1923, 192 T.

The addition of bitumens.

It was recently suggested to the author that, in considering the addition of bitumen to tars for road-making purposes, it is safe to assume that the lower the penetration of the bitumen used, the greater would be the increase in consistency of the tar due to the addition of the bitumen. On investigation, however, it was found that the nature of the bitumen must be taken into account, as well as its penetration.. The various grades of "Texaco bitumen," a petroleum residual manufactured by the Texas Oil Co., Ltd., give particularly striking examples of this influence of the nature of the bitumen, the increase in consistency of a tar due to the introduction of one of these products being much higher than would be expected from a consideration of its penetration alone. This is shown in Table II., which contains representative results obtained with mixtures of 95% of prepared tar with 5% of bitumen.

TABLE II.

Consistency of tar	Bitumen.	Penetration.	Consistency of mixture. Obs	Calc.
36	Texaco No. 9	60	60	46
	Mexphalte	45	48	50
	Trinidad	7	125	125
50	Texaco No. 9	60	80	66
	Mexphalte	45	70	69
	Trinidad	7	140	140
60	Texaco No. 9	60	82	70
	Mexphalte	45	72	73
	Trinidad	7	145	145
68	Texaco No. 9	60	96	78
	Mexphalte	45	80	82
	Trinidad	7	152	152
90	Texaco No. 9	60	145	100
	Mexphalte	45	118	104
	Trinidad	7	175	175

The last column is calculated on the assumption that the increase in consistency varies inversely as the penetration of the bitumen added, the increase due to the addition of Trinidad bitumen being taken as standard.

Hence it follows that if a certain percentage of bitumen is being used in the manufacture of tar-macadam and it is desired to increase the proportion of bitumen without rendering the material more difficult to handle. the use of a softer bitumen will not necessarily solve the difficulty. In every such case it is essential that the actual effect of the bitumen proposed to be used must be determined in the laboratory prior to any definite decision being made.

The effect of heat.

It was suggested in the author's previous paper (*loc. cit.*) that the increase in consistency of a tar when heated might in part be due to the breaking-up of complex compounds with increase in free carbon. On further investigation, however, no evidence of such a change occurring to any appreciable extent could be found; but on analysis of the tar, before and after heating, an unexpected decrease in the percentage of tar acids was noted. This is of interest in view of the recent discussion on the occurrence of phenols in tars produced by the carbonisation of coal at various temperatures. In general this supports the results obtained by Schütz,* Gollmer,† Morgan and Soule,* Hoffmann,† and Currey,‡ showing that the percentage of phenols in tar decreases with increasing temperature of carbonisation.

The method of conducting the experiments to investigate the effect of heat was as follows:—About a gallon of prepared tar was taken for each experiment and after thorough mixing this was divided into two portions. A complete analysis of one portion was carried out in accordance with the Road Board Specification,§ and the other portion was transferred to an ordinary half-gallon can and a reflux condenser connected to the tubulure. The can was surrounded by a water-bath which was slowly heated to boiling, and this temperature maintained over varying periods of time. In this way the tar could be maintained at approximately 100° C. for long periods without the slightest risk of any appreciable loss by evaporation.

The time of heating varied from 8 to 24 hours and the consequent rate of increase in consistency varied from 0·33 to 2·96 secs. per hour, increasing with increase in the consistency of the original tar. The rate of decrease of the tar-acid content does not appear to be related to the original tar consistency, but varied from 0·01 to 0·12% per hour. The results are shown in Table III.

TABLE III.

Expt.	T.	V_1.	V_2.	V_2-V_1.	dV/dT.	A_1.	A_2.	A_1-A_2.	dA/dT.

7	24	220	290	70	2·96	2·4	2·1	0·3	0·02

T = time in hours at 100° C.
V_1 = original consistency. A_1 = original % tar acids.
V_2 = final ,, A_2 = final % ,,

In view of this decrease in the percentage of tar acids present, it was thought advisable to investigate the effect of maintaining tar acids alone at an elevated temperature for a number of hours. This was done, using about 250 c.c. of the crude acids, as extracted from carbolic oil, contained in an ordinary glass flask. No sign of change, however, could be detected in either the physical or chemical properties of the material even after heating to boiling point for 24 hours. In one case a slight decrease in viscosity was noted, but on further investigation it was found that this sample was contaminated with a small percentage of creosote oils. It would thus appear that the change going on in a heated tar is dependent upon the action on the phenols of some other constituents of the tar. This view is supported by the results obtained by heating carbolic oil for some hours at approximately 100° C., when the percentage of phenols as determined by Church's method is decreased by an amount varying with the quantity of phenols originally present. A decrease of as much as 1% in three hours has been noted in the case of an exceptionally rich oil prepared in the laboratory and containing 45% of phenols. It has long ago

§ "General Directions and Specifications relating to the Tar Treatment of Roads," H.M. Stationery Office, 1923.

been suggested* that in the presence of homologues containing the methyl group, phenol itself may be oxidised, with the formation of a triphenylmethane derivative. If this is true, the addition of some oxidising substance to heated tar should bring about an increased change. The passing of hot dry air, free from carbon dioxide, or a mixture of oxygen and air, through tar during distillation has been found to thicken the residue into a "resinified tar."† Although this investigation deals only with temperatures below the temperature of distillation, it seemed possible that even at these lower temperatures the passage of air or oxygen through the tar would lead to an increase in the thickening or "resinification" of the tar if the theory of oxidation is valid; and experimental results obtained by the author have supported this. Table IV. shows the enormous increase in consistency brought about by this passage of air through the tar.

TABLE IV.

T.	V_1.	V^t Without air.	V^t With air.	Δ.
8	50	65	75	20
12	94	98	160	62
12	220	230	360	130
24	94	103	200	97

It has been suggested by Schrader‡ that the phenols present in the low-temperature tar first formed in the distillation of coal, as far as they are not cracked with deposition of carbon, react with the hydrogen present in the distillation gases, being partly reduced, with formation of benzene and its homologues, and partly condensed to high-molecular compounds. It is interesting to note that at the low temperatures employed in the course of the author's experiments there is no evidence of reduction, but rather of oxidation, as already stated. The second reaction supposed by Schrader to take place during carbonisation, however, has been found to occur in the case of tars heated to 100° C., as is shown in the analyses above referred to, by an increase in the percentage of pitch. The results of distillation tests are shown in Table V.

TABLE V.

Expt.	Hours heated.	Water.	Light oil.	Middle oil.	Heavy oil.	Pitch.
1	Nil	Nil	Nil	15·9	5·4	78·6

	24*	0·2	0·2	11·1	6·6	81·9

* Air current passed through.

This is also in accordance with what would be expected from a comparison of the constituents of low- and high-temperature tars.

In conclusion, there is yet a third action which probably takes place, but which the author has not yet been able to prove, namely, the formation of pyrocresols, as shown by Bott* to take place on the distillation of crude phenols.

‡ Chem. Zentr., 1922, 1042.

The tar used throughout the course of this investigation was prepared from horizontal-retort tar obtained from the gasworks at Rhyl, Denbighshire.

Summary.

(1) An earlier statement that granite-dust, limestone-dust, and cement all have an identical effect on the consistency of tars is modified as a result of further investigation, and the final consistency of mixtures containing fillers of the granite-dust type is given by $V_F = V^x$, while the use of limestone-dust leads to a final consistency $V_L = V^{x^4}$

(2) It is suggested that adsorption is the cause of this greater increase in the case of limestone-dust.

(3) The increase in consistency of a tar due to the addition of a bitumen is dependent upon the nature of the bitumen, and not merely upon its penetration. Soft bitumens sometimes produce a greater increase in consistency than do harder bitumens.

(4) If prepared tar is maintained at an elevated temperature over long periods of time, several reactions take place, viz., oxidation of phenols, condensation of phenols to high-molecular compounds, and formation of pyrocresols. These reactions lead to a considerable increase in the consistency of the tar.

NOTE ON THE ACTION OF POTASSIUM CARBONATE ON LEAD GLASS.

BY E. A. COAD-PRYOR, B.A.

H. Droop Richmond, has recently (Analyst, 1923, 48, 200) described some interesting experiments showing the absorption of appreciable quantities of lead and arsenic by potassium carbonate which had been stored in lead glass bottles. The facts which he records serve again to bring into prominence the need for a simple standard test for the suitability of a glass for any particular purpose.

It is well known that glasses vary very considerably in their durability and their resistance to attack by chemical reagents, and it is also well known that though one glass may be more resistant to an acid solution than another, yet it may be less resistant towards alkaline reagents.

Any simple test must, therefore, of necessity give only approximate results if it is to be regarded as a criterion of the general stability of a glass which is used as a container for a variety of different solutions. Fortunately there are a number of tests which will distinguish a really bad bottle, and the choice of a specified test for this purpose is generally determined by the simplicity of the operation and the rapidity with which it can be carried out.

A sample of glass with which Mr. Richmond carried out his experiments was analysed in the present author's laboratory with the following result: SiO_2 67·30%, PbO 13·25%, CaO 2·30%, Al_2O_3 trace, alkalis 17·00%, As_2O_3 0·34%. It was certainly a most unsuitable glass in which to store potassium carbonate. There is no objection, of course, to the use of lead in these bottles—in fact some lead glasses are equal in durability to some of the best chemical resistance glasses.*

For instance, some experiments were carried out with the object of comparing the durability towards chemical reagents of a heavy lead glass of composition:—SiO_2 47·0%, PbO 40·0%, K_2O 7·8%, Na_2O, B_2O_3, Al_2O_3, and CaO traces, with that of the well-known Jena chemical resistance glass.

Losses in mg. per sq. dm.

	Lead-potash	Jena
Boiling water	0·5	0·6
Autoclave, at 183°	10·0	23·0
Hydrochloric acid	3·0	9·6
2*N* Sodium carbonate	57·0	31·5
2*N* Caustic soda	102·0	112·0

It will be seen that as regards any of the tests, with the exception of that with sodium carbonate, the lead glass is the better of the two.

It is necessary, however, to keep the alkali content low—below say, 16%. Where glasses contain lead or arsenic in large quantities, obviously the danger through lack of durability is increased.

With a view of obtaining a comparison between the glass received from Mr. Richmond and a common bottle made from a soda-lime glass, samples of the two glasses were painted with a sludge of damp potassium carbonate and stored for 12 days. Thus the surfaces of the glasses were exposed to a saturated solution of potassium carbonate. At the end of that time the potassium carbonate was washed off the surface and the arsenic in the washings determined. The following results were obtained, calculated as milligrams of arsenic per 100 sq. cm. of glass surface exposed to attack:—Glass from Mr. Richmond 0·0240, soda-lime glass 0·0018, showing a ratio of about 13 to 1 in favour of the soda-lime glass. The latter glass was a bottle glass of medium quality, having an approximate composition of:—SiO_2 75·5%, CaO 8·0%, Al_2O_3 0·7%, Na_2O 15·8%, As_2O_3 0·2%.

Making allowance for the arsenic contents of the two glasses, the soda-lime glass is the better as regards total solubility in the ratio of about 8 to 1. It must not be inferred from these remarks that a soda-lime glass will be superior in durability to any lead glass, but merely to the particular glass in question. There are many medical bottles of "white flint" considerably superior to the bottle (soda-lime) selected for test. The durability increases rapidly with rise in the lime content of the glass, a glass containing 9% of lime being markedly superior to a glass containing 8% of lime, and 10% better still, substituting the lime for the alkali.

Unfortunately the low-lime, high-alkali glasses are very easy to melt and it is the practice of some firms to make a glass containing anything up to 20% of soda and from 5 to 7% of lime. These low-lime glasses have also the advantage, from the manufacturing point of view, that it is easy to obtain a good colour, since one of the principal sources of iron, from which the green colour is derived, is the limestone. The introduction of automatic machinery has made the position still more critical since, on many machines, the high-lime glasses are difficult to work, and it requires great attention to detail and rigorous supervision.

It is therefore desirable that some sort of specification for durability should be established. Even the most discriminating buyer of glassware has no safeguard at the present time that enables him to obtain with any certainty a glass of first-class quality, and manufacturers who go to the trouble and expense of maintaining strict supervision and analytical control, which are necessary for the production of "white flint" glass of a high lime content, are penalised by those manufacturers who, by giving scant attention to the matter, bring disrepute on the glass industry as a whole and particularly on machine-made bottles which, as regards uniformity and accuracy to specified capacity, are far in advance of any bottles which can be made by hand.

A standard test should be simple in operation. Many workers advocate the use of an autoclave test, but, while this test gives valuable results up to a certain point, it entails the use of an expensive apparatus. A promising test appears to be that described by H. S. Blackmore, V. Dimbleby, and W. E. S. Turner,† which consists of exposing the glass to the action of a solution of narcotine hydrochloride for a period not exceeding an hour at 100° C. The durability of the bottle can be estimated by the time which elapses before the solution becomes cloudy and the extent of the cloudiness. With the test carried out as described by the authors, bottles showing no cloudiness until 45 minutes have elapsed might be considered first-class. Bottles which show a faint cloudiness at the end of 20 minutes, but no further increase in the cloudiness at the end of an hour, could be regarded as second grade quality, to be used where no great demand for durability is made.

If this test is proved to be satisfactory from a practical standpoint, it should meet an urgent requirement, and it is to be hoped that users of bottles required for containing chemicals will take the matter up seriously with a view to the establishment of a rational specification. Such a procedure might also be followed with advantage in the case of glass vessels required to contain food.

NOTE ON THE LIDSTONE VISCOSIMETER.

BY GUY BARR, B.A., D.SC.

The "mercurial viscosimeter" described by Lidstone (J., 1917, 270; 1918, 148T) appears likely to find considerable application, not only for the examination of small quantities of material, but also for the determination of the viscosity of dark-coloured liquids, which give a meniscus which cannot readily be observed in an instrument of the Ostwald type. Under these circumstances, it may be well to draw attention to some points connected with the design of the viscosimeter and with the interpretation of the results obtained with it.

The formula obtained by Lidstone in his second paper for the calculation of viscosity from the times of flow observed is derived by making some tacit assumptions which may not be justified in all cases: the full formula is deduced below, and from this it will be possible to find in what cases it may be simplified.

Let V be the volume of the bulb between the fiducial marks used in timing the flow, and let l_a, l_b, and r_a, r_b be respectively the lengths and effective mean radii of the capillary above the bulb through which the liquid is drawn and of the tubing (including stop-cock and jet) below the bulb through which the mercury escapes.

Further, for abbreviation, put

$$\frac{8Vl_a}{\pi r_a^4} = a \qquad \frac{8Vl_b}{\pi r_b^4} = b$$

$$\frac{mV^2}{\pi^2 r_a^4} = p \qquad \frac{mV^2}{\pi^2 r_b^4} = q$$

where m is the coefficient of the kinetic energy term in the amended Poiseuille equation for viscosity.

Now if η_m be the viscosity and d_m the density of mercury at a given temperature, the mean difference of pressure necessary to cause the volume, V, of mercury to flow through the lower tube in a time t will be equal to

$$b\eta_m/t + qd_m/t^2$$

Similarly, for the flow of the liquid through the upper capillary the mean difference of pressure necessary is

$$a\eta_1/t_1 + pd_1/t_1^2$$

where η_1 and d_1 are the viscosity and density of the liquid and t_1 is the observed time for the mercury-liquid meniscus to pass from one fiducial mark to the other in the determination.

A blank run is also made in which the mercury is allowed to run out freely, with no liquid above it. If the height of the mercury column is small compared with the external pressure, we may, to a first approximation, neglect the error due to compressibility of air and write,

$$\text{pressure difference} = a\eta_0/t_0 + pd_0/t_0^2$$

where η_0 and d_0 are the viscosity and density of the air (or air plus vapour in Lidstone's second arrangement).

If H is the mean height of the mercury column and h that of the liquid column during a run, the total pressure difference in the case of the blank run is $P_0 = H(d_m - d_0)g$ and in the case of a run with liquid it is $P_0 + P_1 = H(d_m - d_0)g + h(d_1 - d_0)g$, where g is the acceleration due to gravity.

Hence

$$P_0 = a\eta_0/t_0 + pd_0/t_0^2 + b\eta_m/t_0 + qd_m/t_0^2 \quad \ldots\ldots\ldots\ldots \quad (1)$$

$$P_0 + P_1 = a\eta_1/t_1 + pd_1/t_1^2 + b\eta_m/t_1 + qd_m/t_1^2 \quad \ldots\ldots \quad (2)$$

Substituting for q in equation (2) from (1) we get

$$P_0 + P_1 = a\eta_1/t_1 + pd_1/t_1^2 + b\eta_m/t_1 + t_0^2/t_1^2(P_0 - a\eta_0/t_0 - pd_0/t_0^2 - b\eta_m/t_0)$$

whence

$$\eta_1 = \frac{P_0 t_1}{a}\left\{1 + \frac{P_1}{P_0} - \frac{t_0^2}{t_1^2}\left(1 - \frac{a\eta_0}{P_0 t_0}\right) - \frac{b\eta_m}{P_0 t_1}\left(1 - \frac{t_0}{t_1}\right) - \frac{p}{P_0 t_1^2}(d_1 - d_0)\right\} \quad \ldots\ldots\ldots\ldots \quad (3)$$

This equation will obviously be much simplified if the terms in the large bracket which involve a, b, and p are so small that they may be neglected. If an accuracy of 0·5% is considered ample for the determination of viscosities by this method and η_1 is the viscosity and d_1 the density of the least viscous liquid to be used in the instrument, it will be seen from equation (3) that the term $p(d_1 - d_0)/P_0 t_1^2$ may be omitted provided $pd_1/P_0 t_1^2 < 0.005\ (1 + P_1/P_0)$ or, substituting for t_1 the approximate value $t_1 = a\eta_0/(P_0 + P_1)$ and replacing a and p by their defined values, provided

$$r_a^4 < 0.005\ \frac{64\eta_1^2 l_a^2}{m(P_0 + P_1)d_1} \quad \ldots\ldots\ldots\ldots \quad (4)$$

where m may be taken as unity.

The air friction term $\frac{a_0\eta_0 t}{P_0 t_1^2}$ may be seen to be negligible compared with $1 + P_1/P_0$, since on substituting the approximate value $a = (P_0 + P_1)t_1/\eta_1$, it becomes $\eta_0 t_0/\eta_1 t_1$, where η_0/η_1 is less than 0·1% (taking $\eta_1 = 0{\cdot}2$ poise) and t_0 is less than t_1. If the attempt be made to design an instrument such that it may be used for liquids of fluidity approaching that of water, the term may not be negligible, and it becomes necessary to evaluate a approximately either by direct measurement of the quantities involved in its definition, or, as will usually be easier in a completed viscosimeter, by the following method: Let the instrument be inverted and the capillary and bulb filled with water, the wider tube at the other end of the capillary and the tube through

which the mercury is normally discharged being empty. The temperature being known roughly, let the time, T, required for the water to run out of the bulb be determined. Then writing η_w and d_w for the viscosity and density of the water, we have from Poiseuille's law,

$$\frac{\eta_w}{d_w} = \frac{hg\mathrm{T}}{a} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (5)$$

so that the term $\frac{a\eta_0}{\mathrm{P}_0 t_0}$ is approximately equal to $\frac{hd_w\eta_0\mathrm{T}}{\mathrm{H}d_m\eta_w t_0}$. If the accuracy required is 0·5%, this may be neglected so long as

$$\frac{t_0\mathrm{T}}{t_1^2}\cdot\frac{h}{\mathrm{H}}\cdot\frac{d_w}{d_m}\cdot\frac{\eta_0}{\eta_w} < 0{\cdot}005 \quad \ldots\ldots\ldots \quad (5\mathrm{A})$$

For the term involving b to be negligible we require

$$\frac{8\mathrm{V}l_b}{\pi r_b^4}\cdot\frac{\eta_m}{\mathrm{H}d_m g t_1} < 0{\cdot}005$$

or

$$r_b^4 > \frac{1600\mathrm{V}l_b\eta_m}{\pi\mathrm{H}d_m g t_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (6)$$

If we are designing a viscosimeter to give a certain time of flow t_1 with a liquid of viscosity η_1, we can fix V after deciding on the value of r_a according to (4) by assuming certain values for l_a, h, and H. The lower tube will then be selected so as to have an effective mean radius not less than that specified by equation (6). This tube includes a stopcock and jet: the latter cannot be made unduly large or trouble may be experienced in keeping it full of mercury: consequently it will be best to select a tube and stopcock having a bore considerably greater than the equation demands, and to make the jet taper fairly rapidly. A formula for the resistance offered by a tapering tube to the flow of liquid through it is given by Bond (Proc. Phys. Soc., 1922, 34, 187) from which the effective mean radius of the tube so constructed may be calculated approximately. A direct determination of r_b in a finished viscosimeter offers considerable difficulty, but the value may be deduced with ample accuracy for the present purpose by timing the flow of a liquid of known viscosity, η_s, and density, d_s, through the lower tube: this liquid would naturally be that selected for the calibration of the viscosimeter. The apparatus having been filled by sucking the standard liquid through the jet to the upper fiducial mark, the time, T_1, for the discharge of the volume, V, through the lower tube should be noted. Then, neglecting air friction, we have in addition to

$$\mathrm{H}d_m g = b\eta_m/t_0 + qd_m/t_0^2$$

the similar relation

$$\mathrm{H}d_s g = b\eta_s/\mathrm{T}_1 + qd_s/\mathrm{T}_1^2$$

By eliminating q we find

$$b = \frac{\mathrm{H}d_s g\mathrm{T}_1}{\eta_s}\cdot\frac{1 - t_0^2/\mathrm{T}_1^2}{1 - \frac{t_0\eta_m d_s}{\mathrm{T}_1\eta_s d_m}}$$

Since t_0 will be much smaller than T_1 and $\eta_m d_s$ much smaller than $\eta_s d_m$, tais becomes

$$b = \mathrm{H}d_s g\mathrm{T}_1/\eta_s \quad (7)$$

and the term involving b in equation (3) may be omitted provided

$$\frac{\mathrm{T}_1\eta_m d_s}{t_1\eta_s d_m} < 0{\cdot}005 \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad (8)$$

The criteria (5) and (8) for the negligibility of the air friction and mercury friction terms are of such a form that they may be readily applied to a finished viscosimeter. The viscosity of the least viscous liquid for which the simplified form of equation (3), viz.,

$$\eta_1 = \frac{\mathrm{P}_0 t_1}{a}\left\{1 + \frac{\mathrm{P}_1}{\mathrm{P}_0} - \frac{t_0^2}{t_1^2}\right\}$$

may be used without error due to the omission of the kinetic energy term, is given by substituting in (4) the value of a given by equation (5); thus

$$0{\cdot}005\,\eta_1^2 > \frac{(\mathrm{P}_0 + \mathrm{P}_1)\mathrm{V}\eta_w d_1}{8\pi l_a\mathrm{T}hd_w g}$$

or

$$\eta_1 > \sqrt{\left\{\frac{(\mathrm{H}d_m + hd_1)\mathrm{V}\eta_w d_1}{0{\cdot}04\,\pi l_a\mathrm{T}hd_w}\right\}} \quad \ldots\ldots\ldots \quad (9)$$

The mean heads H and h are measured, for the purpose of this calculation, from the middle of the bulb to the ends of the respective tubes: the discrepancy between these means and the true time averages of the heads is less than 4% for a cylindrical bulb* of length twice that of the efflux tube (*cf.* Bingham, Schlesinger, and Coleman, J. Amer. Chem. Soc., 1916, 38, 27) and just over 2% for a spherical bulb* of diameter twice the length of the tube. A more definite limiting value for η_1 will, of course, be found by calibrating the viscometer with a series of standard liquids, but the above approximation will be useful in limiting the number of standard liquids which are required.

If the viscosimeter is calibrated with a liquid of viscosity η_s and density d_s and its design is such that the simplest formula applies, we have, if t_s be the observed time of flow—

$$\eta_s = \frac{\mathrm{P}_0 t_s}{a}\left\{1 + \frac{hd_s}{\mathrm{H}d_m} - \frac{t_0^2}{t_s^2}\right\}$$

Hence, writing k for P_0/a and n for $h/\mathrm{H}d_m$

$$k = \frac{\eta_s}{t_s}\cdot\frac{1}{1 + nd_s - t_0^2/t_s^2}$$

and the viscosity η of any liquid for which the time of flow is t may be found from the equation

$$\eta = kt(1 + nd - t_0^2/t_1^2).$$

The values of the constants n and t_0 require to be measured, the former by the use of a centimetre scale, the latter by timing the flow of the mercury in a blank run. The equation differs but slightly from that given by Lidstone (1918): it is, however, only applicable if the conditions 5a, 8, and 9 are satisfied.

---

* The formula for the time average, P_s, of the head when the discharge is from a spherical bulb of radius R the centre of which is at a height H above the exit from the capillary is

$$\mathrm{P}_s = \frac{4\mathrm{R}/3}{2c - (c^2 - 1)\log_e\frac{c+1}{c-1}} \quad \text{where } c = \mathrm{H}/\mathrm{R}$$

which may be compared with the corresponding formula for a cylinder of length l_v,

$$\mathrm{P}_s = \frac{l_v}{\log_e\frac{\mathrm{H} + \frac{1}{2}l_v}{\mathrm{H} - \frac{1}{2}l_v}}.$$

Vol. XLIII., No. 8.] **TRANSACTIONS** [February 22, 1924.

THE DETERMINATION OF THE ACTIVITY OF AN ACCELERATOR OF VULCANISATION.*

BY G. MARTIN, B.SC., A.I.C., AND W. S. DAVEY, B.SC., A.I.C.

The chief difficulty encountered in comparing the activity of different accelerators is that they are used for a variety of purposes and in a still larger number of mixes. It does not follow that if accelerators are arranged in order of effectiveness in one mix they will have the same relative order of effectiveness in another mix. Although at the present stage of our knowledge this is an almost insuperable difficulty, classification on broad lines is possible. On questions of detail there is no doubt that individual accelerators require individual experiments.

In addition to the thousands of mixes in which accelerators may have to function, they may also be used under a variety of curing conditions. The simplest and the most generally applicable mix is one containing rubber, sulphur, zinc oxide, and accelerator, and the most generally applicable conditions are vulcanisation in steel moulds under hydraulic pressure in steam. The factors affecting the activity of the accelerator in this mix and in these conditions are:—

1. The purity, concentration, and specific surface of the substances used.
2. The temperature of vulcanisation.

It is proposed to consider these factors in detail.

Purity.

The ingredients of the mix other than rubber are substances of definite chemical composition, the purity of which can and should be checked before using. On the other hand, raw rubber contains small and varying quantities of valuable natural products, some of which affect the activity of the accelerator.

The authors[1] have shown that in the presence of zinc oxide and an accelerator, some of the acetone-soluble substances present in raw rubber have a remarkable effect on the physical properties of the vulcanised rubber. Thus in the mix 90 rubber, 10 sulphur, 5 zinc oxide, 1 thiocarbanilide, it was found that good physical properties were obtained when 0·9% of sulphur had combined with the rubber, whereas in the case of another rubber over 5·0% of combined sulphur was necessary to produce a similar physical effect, as judged by the elongation at the standard load; and it was found that the rubbers which required a relatively small quantity of combined sulphur were the rubbers which gave strong vulcanised products, while those requiring the most combined sulphur gave weak products even at the maximum tensile strength cure.

In a recent paper Sebrell and Vogt[2] stated that a deficiency of resin acids in raw rubber gives stocks of poor physical properties. Experiments at the Imperial Institute indicate that the addition of certain long-chain fatty acids to a hexamethylenetetramine mix containing 5% sulphur and 5% zinc oxide results in a considerable acceleration of vulcanisation when the natural acids are absent (acetone-extracted rubber), but has little effect on vulcanisation in the presence of normal amounts of the natural acids. In the presence of an equal quantity by weight of rubber and zinc oxide, vulcanisation proceeds normally whether the resin acids are present or absent. The explanation of these phenomena may be connected with the chemical action of the so-called heveic acid[3] on the zinc oxide forming a soap solution in the rubber.[4] Similar zinc salts have been shown by Bedford and Gray[5] to be capable of replacing zinc oxide. The effect of resin acids appears therefore to be tantamount to increasing the zinc surface available for the formation and stabilisation of the catalyst and for the production of the physical effects associated with an increased amount of zinc oxide. In the presence of large quantities of zinc oxide the space between the particles is reduced by an amount which may be considerably more than the percentage increase in concentration, so that eventually diffusion and surface effects and therefore vulcanisation proceed unaffected by moderate variations in the available surface of zinc oxide.

The differences developed in the physical properties of the vulcanisate with different rubbers seem to be independent of the nature and amount of the accelerator.[6] Although increasing the amount of zinc oxide renders the results much more uniform, there is still a certain amount of variation, which is not connected with the acetone-soluble substances present in raw rubber. Thus in the mix 90 rubber, 90 zinc oxide, 5 sulphur, 1 hexamethylenetetramine, the time required to bring 2% of sulphur into combination with rubber at 148° C. is about 25 minutes for a rubber containing all the latex by-products, and 30 to 50 minutes for different samples of plantation rubber.

In determining the activity of an accelerator, it is evident that, irrespective of the amount of zinc oxide present, the results will be affected by the chemical composition of the raw rubber. In the presence of a large amount of zinc oxide, however, this variation is reduced considerably, especially when comparisons are based on physical standards of cure.

For this reason and also for the purpose of bringing out the full activity of an accelerator, a mix contain-

[6] Martin and Davey, *loc. cit.*

ing equal proportions by weight of rubber and zinc oxide is more satisfactory for the comparison of accelerators than one containing only small amounts of zinc oxide.

Concentration.

(*a*) *Accelerator.*—If the concentration of the accelerator is doubled, it is generally realised that the rate of combination of rubber and sulphur is not doubled. The acceleration factor for aldehyde-ammonia in the rubber : sulphur mix (90 : 10) has been shown by Twiss and Brazier[7] to be increased by 76%, 66%, and 50% respectively on repeatedly doubling the concentration of the accelerator. The authors mention that the vaporisation of the aldehyde-ammonia during mixing probably had an influence on the results. In the following table, compiled from work done at the Imperial Institute, is shown the percentage increase in the rate of combination of rubber and sulphur obtained by doubling the concentration of the accelerator in a mix containing equal quantities by weight of rubber and zinc oxide.

TABLE I.

Mix: 90 rubber, 90 zinc oxide. Temperature 141° C.

	10 Sulphur.	7½ Sulphur.	5 Sulphur.
Aldehyde-ammonia	33	25	25
Hexamethylenetetramine	30, 29	31, 25	-
"Supatac"	25	31	32
p-Phenylenediamine	--	31	30
"Accelerene"	-	38	--

The vulcanisation coefficient of each sample was determined at a value approximately 2·0, and a correction made for any deviation from this value. A small error in mixing or curing causing an error amounting to 1% of the total amount of combined sulphur will raise or lower the figures shown in the table by three units.

The results indicate that the increase in activity of the above accelerators on doubling their concentration is fairly uniform. Confirmation of this conclusion was obtained in the presence of still smaller quantities of sulphur. It follows that if a given quantity of accelerator A is found to enable sulphur to combine with rubber 30% more quickly than the same quantity of accelerator B under the conditions observed above, then half the quantity of accelerator A has the same activity as accelerator B. The results suggest that it may be possible to obtain an accelerator constant which is independent of the accelerator concentration.

(*b*) *Zinc oxide.*—The diminished activity of unit quantity of accelerator on increasing its concentration may be connected with surface phenomena. It is to be expected that in those cases where the accelerator functions through the formation of a zinc salt stabilised by the presence of zinc oxide, diminishing or increasing the concentration of the zinc oxide will have some effect on the rate of combination of rubber and sulphur.

It is interesting to note therefore that in the case of piperidinium pentamethylenedithiocarbamate Twiss and his collaborators[8] found that 1% of zinc oxide greatly increased the potency of the accelerator. The addition of a further 4% of zinc oxide increased its potency by approximately 50%, and a still further addition of 15%, making 20% altogether, gave a still further increase in activity of nearly 10%. It is evident that the effect of increasing the concentration of zinc oxide in the case of this accelerator is to increase the rate of combination of rubber and sulphur at a rapidly decreasing rate. It may be expected therefore that when the concentration of the zinc oxide exceeds a certain amount, further addition of zinc oxide will have little effect on the rate of combination of rubber and sulphur. The mix selected for the majority of the experiments described in this paper contains a large amount of zinc oxide, so that small variations in the amount present are not likely to affect the results.

(*c*) *Sulphur.*—The rate of combination of rubber and sulphur is markedly affected by the concentration of the sulphur. According to Fol and van Heurn[9] in a rubber-sulphur mix the rate is nearly proportional to the amount of sulphur present. The following table shows the variation in rate of combination of rubber and sulphur in a mix containing equal quantities by weight of rubber and zinc oxide, a fixed amount of accelerator, and varying amounts of sulphur. It will be seen that the rate of combination of rubber and sulphur increases with the concentration of the sulphur, but is not directly proportional except in the case of *p*-phenylenediamine.

TABLE II.

Accelerator.	Accelerator concentration %	Sulphur concentration %	Rate of combination of rubber and sulphur per minute. %	Rate of combination of rubber and sulphur per unit of sulphur present. %
Hexamethylenetetramine	1·11	11·11	0·0925	0·0083
		8·33	0·0738	0·0089
		5·56	0·0427	0·0077
		3·33	0·0256	0·0077
Aldehyde-ammonia	1·11	11·11	0·0805	0·0083
		8·33	0·0805	0·0097
		5·56	0·0595	0·0107
		3·33	0·0222	0·0067
p-Phenylenediamine	1·11	8·33	0·0590	0·0071
		5·56	0·0400	0·0072
		3·33	0·0228	0·0069
Thiocarbanilide	4·44	8·33	0·0840	0·0102
		5·56	0·0706	0·0127
		3·33	0·0260	0·0078

It may be mentioned that in carrying out these tests, no attempt was made to use the same raw rubber for the different accelerators, as the object in view at the time of the experiments was not the comparison of accelerator activities.

Specific surface.

The effect on vulcanisation of the state of dispersion of the zinc oxide is said to be considerable in the absence of an added accelerator. Very little work on this subject has been published.

Temperature.

In connexion with the effect of temperature on the rate of vulcanisation, Twiss and his collaborators[10] state: "The fact that the temperature coefficient

[7] J., 1920, 129T.
[8] J., 1922, 81T.

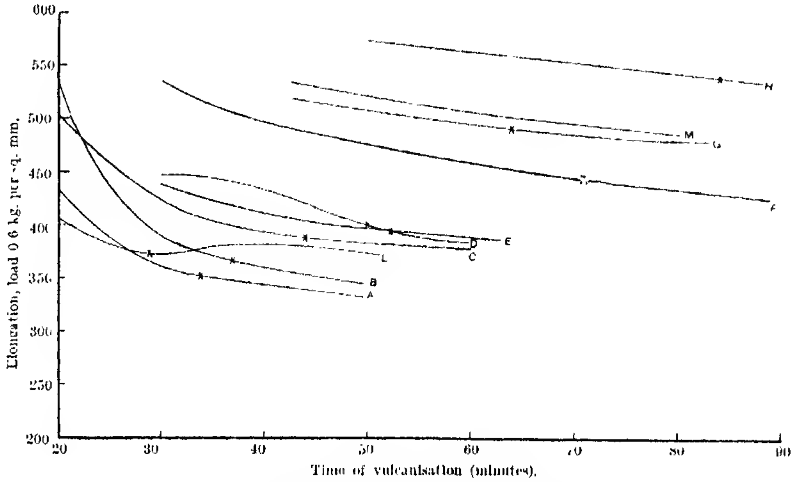
[9] Delft Communications, 6, 189.
[10] *Loc. cit.*

possesses comparable values for mixings with and without an artificial catalyst appears . . . to be a general one for all catalysts." In the case of a mix containing piperidinium pentamethylenedithiocarbamate the same authors state: "These figures indicate that for a mixture containing sufficient zinc oxide a fall of 10° C. in the temperature necessitates a period of vulcanisation 2-2½ times as long; the value is comparable with that found for the temperature coefficient of vulcanisation of simple mixtures containing simple accelerators. . ."

There are, of course, upper limits of temperature, fixed by circumstances of stability, beyond which accelerators will not follow the above law. At lower temperatures the insolubility of sulphur and accelerator are complicating factors.

The conclusions of Twiss and his collaborators in the case of zinc oxide mixings are based on physical measurements of the rate of cure. Chemical measurements of the rate of cure of zinc oxide mixings are insufficient to draw general conclusions. containing large quantities of zinc oxide the variation is greatly reduced, and in the case of the accelerators for which results are given in the accompanying figure, a relation can be traced between the rate of change in physical properties per unit of combined sulphur and the rate of combination of rubber and sulphur.

The quicker the rate of combination of rubber and sulphur, the less sulphur is required to bring about the physical changes associated with vulcanisation. Hence ultra-accelerators require very little sulphur. There is no independent evidence to show that this is connected with the reduced heat treatment required. When accelerators are present in equivalent amounts the elongation-cure curves appear to be approximately the same. Shepard and Krall[11] found differences in the vulcanisation coefficients when accelerators were present in amounts sufficient to give the same stress-strain curve in the same time. It follows therefore that different accelerators have specific effects on the physical properties of



The mark **x** shows the point in the curve corresponding with a vulcanisation coefficient of 2·0.

Comparison of results of chemical and physical tests.

It should be emphasised that there is a difficulty in correlating the results of physical tests with those of chemical tests. It is now well established that in mixes of the type under discussion the physical changes associated with vulcanisation are brought about with a lower percentage of combined sulphur than in the case of rubber sulphur mixes, and that the physical change corresponding with a given vulcanisation coefficient is dependent upon the accelerator used. The authors have recently shown that in the case of mixings containing only small quantities of zinc oxide the physical changes per unit of combined sulphur vary considerably with the raw rubber used. In the case of mixings vulcanised rubber. This receives some support in the results obtained above with thiocarbanilide. The nature of the accelerator does not, however, appear to be as important a factor as the rate of combination of rubber and sulphur.

The quicker the rate of combination of rubber and sulphur, still more quickly are produced the physical effects associated with vulcanisation, so that the results of physical tests give a greater value for accelerator activity than the results of combined sulphur determinations.

From the curves shown it may be inferred that there is a relation which will allow the two sets of results to be correlated.

[11] J. Ind. Eng. Chem., 1922, 14, 951

Acceleration factor.

Some investigators[12] have made use of an acceleration factor as follows: $k = S_a/S_r$, where k is the acceleration factor, S_a is the rate of vulcanisation in the presence of the accelerator, and S_r is the rate of vulcanisation in the same mixing in the absence of the accelerator.

In this paper, to avoid the complications connected with the difference between physical and chemical measurements of rate of cure, S_a and S_r are regarded as referring to the rate of combination of rubber and sulphur and not to the physical effects produced.

Such an acceleration factor is useful if its limitations and approximations are understood. It is dependent upon the ratio of two values both of which are affected by the raw rubber used and not always in the same direction. The greater the acceleration factor the less seriously is its value affected. Moreover, the variation can be distinctly reduced if thin crêpe rubber, which requires a long time of cure in the rubber-sulphur mix, is always employed when making determinations. The value of the acceleration factor is also affected, but not to a large extent, by the concentration of the sulphur and possibly by the temperature of vulcanisation. The most uniform results are obtained in the presence of large quantities of zinc oxide.

The value found for the acceleration factor is, of course, affected considerably by the concentration of the accelerator. In view of the indications obtained of the connexion between the concentration of the accelerator and the rate of combination of rubber and sulphur in the zinc oxide mixing described it is suggested that the term "potency" should be reserved to describe the acceleration factor found for a 1% concentration of the accelerator in the rubber. By suitable adjustments of temperature this can be actually determined, or it can be calculated from the formula $K = k/A^{1/n}$ where K is the potency of the accelerator, k the acceleration factor, and A the percentage concentration of the accelerator in the rubber; n has a value of about 2·6 (calculated from the results in Table 1).

The potency of an accelerator is not strictly constant under varying conditions. It should, however, be useful for the purpose of commercial descriptions.

THE ESSENTIAL OIL OF MANUKA (*LEPTOSPERMUM SCOPARIUM*).

BY ROY GARDNER, M.SC.

The shrub known as "manuka" (*Leptospermum scoparium*, Forst.) is the dominant plant on heathlands in New Zealand and covers thousands of acres of land, much of which is of little use for agricultural purposes. The oil-glands in the leaves are apparent to the naked eye. Distillation on a commercial scale would not be difficult if the oil should prove to be of sufficient value; an investigation of it has therefore been made.

The only previous investigation of which any record can be found was made by Atkinson (Pharm. J., 4, 15, 369), who gives saponification and bromination values for several fractions, but apparently came to no conclusion as to the composition of the oil.

The samples referred to in this paper were obtained from plants growing practically at sea-level, on basaltic soil at Dunedin, and were collected between March and August. No attempt has been made to investigate the influence of situation, season, or varietal differences in the plants on the yield or nature of the oil.

The leaves and branchlets were treated with superheated steam at about 120°—150° C. and the oil floated off the condensed water, the average yield being 0·45%. The largest sample of oil used in this investigation was about 170 grams.

The oil is pale greenish-yellow in colour; it has $n_D = 1{\cdot}50$; d^{15} 0·921; the approximate boiling-range at atmospheric pressure is 160°—270°. The oil was shaken out with sodium hydroxide solution; the aqueous layer on acidification gave a liquid phenol (fraction 0, below) and the unabsorbed oil was fractionally distilled *in vacuo*. The appended table gives the result after three distillations.

Fraction.	% by wt.	B.p. 15 mm.	Colour.	n_D approx.	$d^{15/15}$	$[\alpha]_D^{22}$	Gram-equivs. of ester per 1000 g.
0.	2·8	140°-170°	Brown	1·505	1·059	0	—
I.	2·8	65°-98°	Colourless	1·485	0·830	+ 4·7°	—
II.	6·7	98°-135°	Colourless	1·510	0·926	+ 5·3°	2·9
III.	29·9	135°-145°	Pale yellow	1·517	0·933	+ 9·9°	1·4
IV.	42·2	145°-150°	Pale yellow-green	1·517	0·930	+ 14·5°	0·4
V.	8·4	150°-160°	Green	1·550	0·934	—	1·6
VI.	7·7	above 160°	Dark (semi-solid)	—	—	—	—

The saponification values were determined by boiling on the water-bath with standard alcoholic potash for half-an-hour. Saponification for two hours in the cold gave much lower values. The above figures were not altered by acetylation, showing the absence of free alcohol.

A long series of fractional distillations at atmospheric pressure failed to give any more definite separations.

The following substances were identified:—

Phenolic constituent. The phenolic substance (Fraction 0) gave a red colour with ferric chloride and a deep blue with copper sulphate. The quantity was too small for purification, but the major constituent is undoubtedly leptospermol, a phenol isolated by Penfold from the oil of *Leptospermum flavescens* (Proc. Roy. Soc. N.S.W., 1921, 49). The characters of the present fraction are here given, those given by Penfold for leptospermol being added in brackets: b.p. (10 mm.) 140°—170° (145°—146°); colour with ferric chloride, orange-red (orange-red); colour with copper sulphate deep blue (deep blue); d 1·059 (1·073); $[\alpha]_D = 0°$ (0°); $n_D = 1{\cdot}50$ (1·5000); molecular weight by freezing-point method 261 ($C_{14}H_{20}O_4 = 252$).

Terpene. Fraction I. consisted almost certainly of terpenes, the odour suggesting pinene. The

largest sample obtained—less than 4 g.—was allowed to stand in a corked flask for some months, before examination; this fraction was then found to have absorbed oxygen and formed a viscous material resembling old turpentine.

Cinnamic esters. These are present principally in Fraction III., and to a less extent in Fractions II. and IV. On warming with alcoholic potash, potassium cinnamate separates. The acid was obtained and identified by determination of equivalent, by oxidation to benzaldehyde, and by mixed-melting-point tests. It is presumably present as its ethyl or methyl ester, but as little saponification takes place even on long boiling with aqueous alkali this point was not decided. The quantity of acid obtained corresponded with the presence of 4·8% of ethyl cinnamate in the oil.

Other esters. The esters present, particularly in Fractions II. and III., gave on saponification an alcohol having a fine rose-like odour, and acetic acid mixed with other acids, probably including butyric acid, was recovered from the potassium salts. Attempts to separate the alcohol from the sesquiterpene with which it is mixed have not yet been successful. Prolonged boiling of the material with phthalic anhydride gave no result, nor did treatment with anhydrous calcium chloride in a freezing mixture for the extraction of geraniol. When the material was shaken with 50% resorcinol solution (which absorbs several terpene alcohols and other oxygenated compounds), and the aqueous layer steam-distilled, a few drops of rose-scented liquid were obtained, but the quantity was too small for identification.

Sesquiterpene. The greater part of the oil consists of sesquiterpene. A fairly pure specimen was obtained by allowing the oil (after saponification, and separation of acids and phenols) to stand over sodium for several days, heating with sodium for an hour, separating the liquid as completely as possible from the sodium and from the semi-solid substances which had formed, and distilling *in vacuo.* This material gave C 87·8%, H 11·7%, molecular weight 203; $C_{15}H_{24}$ requires C 88·16%, H 11·84%, mol. wt. 204.

This sesquiterpene gives the beautiful colour-reactions characteristic of aromadendrene, the characteristic sesquiterpene of the Eucalypts and also found in several of the Leptosperms, which belong to the same sub-order of the *Myrtaceæ* as do the Eucalypts *cf.* Baker and Smith, "Eucalypts and their Essential Oils," Sydney, 1920). The physical constants are appended, with those (in brackets) given by Penfold (Proc. Roy. Soc. N.S.W., 1920, **54**, 197) for aromadendrene:—B.p. 122°—128° at 11 mm. (123°—125° at 10 mm.); d^{20} 0·913 (d^{15} 0·910); n_D=1·50 (1·4967); $[\alpha]_D$=−12·8°. Aromadendrene from a Eucalypt gave $[\alpha]_D$=+4·7° (Smith, *op. cit.*) and from *Leptospermum flavescens* —6·2° (Penfold, *loc. cit.*).

It has been found, however, that the sesquiterpene of the present oil on treatment in ethereal solution with hydrochloric acid gas gives a definite liquid monohydrochloride, b.p. about 160° at 10 mm. (found Cl=14·4%, $C_{15}H_{24}$.HCl requires 14·8%). As no such derivative appears to have been prepared from aromadendrene (of which, indeed, no definite derivatives are known), it would seem either that the sesquiterpene here described is similar to, but not identical with, aromadendrene, or that this hydrochloride is the first derivative of aromadendrene to be prepared. This point must be left open at present, but is being further investigated.

Semi-solid, non-volatile material. No definite substance was obtained from this (Fraction VI.). Combustion gave C 73·9%, H 10·5%, and the average molecular weight is about 360. No conclusion has been arrived at as to the nature of the substances present.

Summary.

The following is the approximate composition of the oil:—

	%
Phenols (leptospermol)	2·8
Terpenes	2·8
Esters of cinnamic acid, calculated as ethyl cinnamate	4·8
Other esters (acetic etc. esters of alcohol, unidentified, of rose odour) calculated as $CH_3COOC_{10}H_{15}$	12·9
Semi-solid, non-volatile matter	7·7
Sesquiterpene (by difference)	69·0
	100·0

The sesquiterpene agrees in character with aromadendrene and gives the colour reactions characteristic of that substance, but yields a definite liquid monohydrochloride.

In conclusion I desire to record my indebtedness to Professor Worley, of Auckland University College, for an arrangement which prevented overlapping, and to express my sincere thanks to Professor Inglis, of this University, for his helpful interest in the work.

THE DETERMINATION OF PENTOSANS IN WOOD CELLULOSE.

BY WALTER JAMES POWELL AND HENRY WHITTAKER.

The method which is at present in general use for the determination of pentosans in wood cellulose consists in distilling a known weight of the sample with 12% hydrochloric acid until no more furfural is evolved, as indicated by the absence of a pink coloration with aniline acetate. The furfural in the distillate is then determined by precipitation of its compound with phloroglucinol. After warming and standing overnight, the phloroglucide is collected on a Gooch crucible, washed free from acid, dried, and weighed. The composition of this compound is not definitely known, and a factor is used

to calculate the weight of furfural, whilst a correction must also be made for the solubility of the phloroglucide in the mother liquor. Accurate results are obtained, but the method is tedious, as much as three days being necessary to complete a determination. The volumetric method now described is based on a definite reaction between furfural and bromine. By its means consistent results in close agreement with those given by the gravimetric method are obtained, and the analysis can be completed in a single day.

At first an attempt was made to modify the existing method in the following way. To the distillate a known excess of a standard solution of phloroglucinol in 12% hydrochloric acid was added, and after standing for one hour a known amount of $N/10$ sodium bromide-bromate solution was added to an aliquot portion. The excess of bromine was then determined by means of potassium iodide and $N/10$ sodium thiosulphate. It was hoped in this way to determine the uncombined phloroglucinol, the assumption being made that the latter would react quantitatively with bromine. The preliminary experiments showed, however, that furfural and phloroglucinol only react very slowly at the ordinary temperature and, further, that furfural itself reacts quantitatively with bromine in dilute acid solution. It has now been found that it can be readily determined by this reaction, in which one molecule of furfural combines with four atoms of bromine.

Since the completion of this work, our attention has been drawn to a paper by Pervier and Gortner (Ind Eng. Chem., 1923, 15, 1167, 1255) in which a method based on a similar reaction is described. These authors determine furfural in the distillate by adjusting the acidity of the latter to 4%, and adding $N/10$ bromide-bromate slowly from a burette until a trace of free bromine is present. The end point is determined electrometrically. Under these conditions they found that one molecule of furfural reacts with two atoms of bromine, from which a simple conversion factor for c.c. of bromide-bromate to grams of furfural is calculated.

These authors state (*loc. cit.*, 1256, footnote) that they were unable to secure satisfactory results in the determination of furfural by any method involving the addition of an excess of bromine. The experience of the present authors, however, indicates that an accurate and simple determination of furfural can be made by adding an excess of bromine. In these circumstances the limit of the reaction is expressed by one molecule of furfural using four atoms of bromine. In 10% hydrochloric acid this limit is soon reached, and consistent results have been obtained when the reacting solution has been allowed to stand for periods varying from one to twenty-four hours. The fact that one molecule of furfural reacts with four atoms of bromine when the latter is present in excess explains why Pervier and Gortner (*loc. cit.*) experienced difficulty in obtaining a satisfactory end point in their titration, unless the rate of addition of the bromide-bromate was very carefully adjusted.

Details of method.—0·5–0·8 g. of material is distilled with 12% hydrochloric acid until the distillate gives no further coloration with aniline acetate. The distillate is then made up to 500 c.c. with 12% hydrochloric acid. It may be noted that the presence of cork or rubber in the distillation apparatus leads to inaccuracies, and all connexions should be of glass. Into each of four well-stoppered bottles are pipetted 25 c.c. of the standard, approximately $N/10$ sodium bromide-bromate solution. To two of these bottles there are now added 200 c.c. of the distillate and to the other bottles 200 c.c. of 12% hydrochloric acid. The bottles are allowed to stand in the dark for one hour, and after the addition of 10 c.c. of 10% potassium iodide solution, the liberated iodine is determined by titration with $N/10$ sodium thiosulphate. The number of c.c. required by the sample is subtracted from the number of c.c. required by the blank, the difference being a measure of the furfural present. The method was standardised against a solution of pure redistilled furfural in 12% hydrochloric acid (1 c.c. of solution contained 0·00206 g. of furfural). It was found that 10 c.c. of this solution required 8·6 c.c. of $N/10$ sodium thiosulphate, *i e.*, 1 g.-mol.of furfural reacts with 4·05 g.-atoms of bromine.

In calculating the following results it has been assumed, therefore, that 1 mol. of furfural reacts with 4 atoms of bromine, *i.e.*, 1 c.c. of $N/10$ sodium thiosulphate is equivalent to 0·0024 g. of furfural.

Comparative determinations of furfural in the same sample have been carried out by the gravimetric and volumetric methods, and the results obtained are shown in the following table:—

Material.	Furfural, %. Gravimetric method.	Furfural, %. Volumetric method.
1. Easy bleaching sulphite cellulose	2·95	2·70
2. Klered bleached sulphite cellulose	1·75	1·76
3. Bleached sulphate cellulose	3·20	3·40
4. Bleached poplar soda cellulose	7·47	7·38
5. Unbleached poplar soda cellulose	6·00	6·20
6. Purified ash sawdust	9·40	9·62
7. Purified ash sawdust (different sample)	8·30	8·00
8. Easy bleaching soda cellulose	5·00	5·09
9. Sulphate cellulose	6·03 6·04 6·10	6.06 5·99
10. Unbleached spruce soda cellulose	1·80	1·85

This investigation was carried out in the Research Department, Royal Arsenal, Woolwich. The results are published by permission of the Director of Artillery, to whom our thanks are due.

Vol. XLIII., No. 9.] TRANSACTIONS [February 29, 1924.

THE DESULPHURISATION OF IRON PYRITES.

BY F. C. THOMPSON, D.MET., B.SC., AND NORMAN TILLING, M.SC.

The present ore reserves of ferrous materials have been estimated to be equivalent to about 500 years' supply at the present rate of consumption. If, however, the rate of increase during the past few decades holds, the supply would be sufficient for much less time. It is, perhaps, less the total supply which is of interest in many quarters than the amount available of the low-sulphur ore suitable for the production of steel. It appeared, therefore, that it would be of some interest to investigate the problem of the desulphurisation of iron ores from a laboratory point of view, and to this end the present paper—the first, it is hoped, of a series bearing on the same problem—deals with the removal of sulphur from iron pyrites. If an adequate removal could be effected by an economically useful method the iron ore reserves suitable for the production of a pig iron available for the production of acid steel, would be considerably increased.

Present methods of desulphurisation of iron ores. Treatment of ores before charging into the blast furnace.

(*a*) *Magnetic concentration.*—This treatment not only removes a considerable proportion of the gangue, but it has the additional advantage of eliminating a large proportion of the phosphorus, and, in some cases also, the sulphur that is present in the original ore. It is stated that when sulphur is present in the form of pyrites it is more readily removed by magnetic concentration than by calcination. This method is used in the treatment of Lake Superior ores, and of the magnetites of Sweden, where apatite and pyrites exist in the form of separate particles. It does not, however, yield such good results with British ores, since the phosphate, silica, and sulphide are in a state of fine division, and are intimately associated with the ore.

(*b*) *Weathering.*—The process has a twofold object: (1) removal of shale; (2) removal of sulphur. Weathering is uncommon, but is carried on in Sweden, where ores containing sulphur in the form of pyrites are left exposed to the atmosphere. The sulphide is oxidised to ferrous sulphate, which is soluble, and is carried away by the rain.

Materials containing both lime and sulphur should not be weathered, since the ferrous sulphate formed would interact with the lime yielding calcium sulphate, which is insoluble, and would not be washed away.

(*c*) *Calcination.*—One of the objects of this treatment is to eliminate sulphur. The ore is roasted in an oxidising atmosphere, so that at any rate some of the sulphide present is oxidised and the sulphur expelled.

S. G. Valentine[1] carried out a series of experiments on the calcination of iron ores containing pyrites. Such ores can be satisfactorily desulphurised if there is free access of air during roasting; in the absence of air only one-half of the sulphur in the pyrites, at the most, is eliminated. Sulphates of iron are decomposed equally well, whether air is present or absent, so that, if the ore be sufficiently oxidised in the preliminary stages of calcination, desulphurisation may be completed in a neutral atmosphere.

The magnetic ore of Cornwall Banks in Pennsylvania contains about 2·5–3·25% of sulphur. On calcination the sulphur is reduced to about one-twentieth of that in the native ore. It is thus possible by efficient calcination very considerably to diminish the percentage of sulphur in many iron ores.

Desulphurisation in the blast furnace.

Usually not more than one-twentieth of the sulphur present in the charge passes into the iron. Turner[2] has considered the conditions affecting the absorption of sulphur, and has arrived at the following conclusions: (*a*) A high temperature prevents the absorption of sulphur by iron. (*b*) A basic slag readily combines with the sulphur. (*c*) The amount of sulphur actually retained in the iron on cooling is influenced by the proportions of silicon, manganese, and possibly other elements present in the metal, these elements tending to exclude sulphur.

For every proportion of silicon there is a certain proportion of sulphur, which cannot be exceeded in cast iron under normal conditions. Hilgenstock[3] confirmed these observations, the desulphurising effect of manganese being more marked than that of silicon.

As the materials pass down the furnace, sulphur from the coke is absorbed by ferric oxide the action being quite evident at about 250° C. From 800° C. upwards the action is reversed, and lime becomes the chief absorbent of sulphur, the affinity of lime for sulphur increasing as the temperature rises.

Desulphurisation of pyrites in the manufacture of sulphuric acid.[4]

Insufficient air causes sulphur to distil. The burning of pyrites in this process reduces the sulphur in the cinders with good work to 3 or 4%, or even less with very good ores.

Dissociation pressure of iron pyrites.

E. T. Allen and R. H. Lombard[5] have determined experimentally the dissociation pressure of FeS_2 by a method which depends on balancing the dissociation pressure of the sulphide against the vapour pressure of sulphur at known temperatures. They found that the dissociation pressure of pyrites over a range of pressure of 1 mm. to 500 mm., increased from 0·75 mm. at 575° C. to 518 mm. at 680°. The dissociation may be represented by the equation :—

$$FeS_2 = FeS + S.$$

Vapour pressures of sulphur dioxide, sulphur trioxide, and oxygen over heated iron sulphates ; and the equilibrium $2SO_3 \rightleftarrows 2SO_2 + O_2$.

M. Bodenstein and W. Pohl[6] investigated the equilibrium $2SO_3 \rightleftarrows 2SO_2 + O_2$, and obtained values for the equilibrium constant $K = (C^2_{SO_2} \times C_{O_2})/C^2_{SO_3}$ for temperatures ranging from 528° to 897° C. By plotting log K values against temperature the values of K may be obtained for intermediate temperatures.

G. Keppeler and J. D'Ans[7] investigated the vapour pressure of sulphur dioxide, sulphur trioxide, and oxygen overheated ferric sulphate, the basic sulphate, $Fe_2O_3,2SO_3$, and ferrous sulphate. A current of air or nitrogen was passed through a tube containing anhydrous sulphate heated to a definite temperature, and the proportions of SO_2 and SO_3 in the issuing gas were determined. From their results the equilibrium between $Fe_2(SO_4)_3$ and SO_3 is best represented by :—

$$Fe_2(SO_4)_3 \rightleftarrows Fe_2O_3 + 3SO_3.$$

In the gaseous phase the equilibrium $2SO_3 \rightleftarrows 2SO_2 + O_2$ is established, and the equilibrium constants are in agreement with the values given by Bodenstein and Pohl.

The pressure of SO_3 over basic ferric sulphate, $Fe_2O_3,2SO_3$, is greater than over normal ferric sulphate at the same temperature, and the former is regarded as a labile compound. In the gaseous phase at lower temperatures the expected equilibrium was not reached ; too much SO_2 was found in all cases.

The behaviour of ferrous sulphate is best represented by the equation $2FeSO_4 \rightleftarrows Fe_2O_3,SO_3 + SO_2$. In the gaseous phase above $FeSO_4$ at high temperatures there is a constant ratio between the partial pressures of SO_2 and SO_3. The graphs obtained by plotting vapour pressures against temperature are shown in Figs. 12 and 13.

L. Wöhler, W. Plüddemann, and P. Wöhler[8] used a static method in the determination of the vapour pressures of the sulphates. The total pressure of the system at a known temperature was determined, and the partial pressures of SO_3 and SO_2 were calculated from Bodenstein and Pohl's measurements.

To ascertain whether $Fe_2(SO_4)_3$ was decomposed directly into Fe_2O_3 and SO_3, the basic sulphate Fe_2O_3,SO_3 was heated, and the vapour pressures found at three different temperatures agreed with those found for $Fe_2(SO_4)_3$, thus showing that a basic sulphate is not formed, and that there is no evidence for the formation of a solid solution of oxide and sulphate.

M. Bodenstein and T. Suzuki[9] repeated the experiments of Keppeler and D'Ans, and of Wöhler, Plüddemann, and Wöhler, and obtained results in agreement with the original measurements in both cases. The measurements by the static method of the partial pressure of SO_3 in equilibrium with $Fe_2(SO_4)_3$ give values three or more times as large as those obtained by the dynamic method of Keppeler and D'Ans. In Wöhler's method it is shown that the gases are really in equilibrium, and, therefore, the calculation of the partial pressures of SO_3 and SO_2 is justifiable. In Keppeler's method the ratio between the oxides of sulphur and oxygen is not in agreement with Bodenstein and Pohl's measurements of the dissociation of SO_3 ; there is always too little SO_3. The deviation diminishes as the temperature rises, and it appears, therefore, that the low results obtained by Keppeler are due to equilibrium not being established. If $Fe_2(SO_4)_3$ dissociates directly to Fe_2O_3 and SO_3, an excess of SO_3 would be anticipated, instead of a deficit, and hence the mechanism of the reaction is probably more complicated.

L. Wöhler and M. Grünzweig[10] improved the apparatus previously used by Wöhler, Plüddemann, and Wöhler. The measurements with $Fe_2(SO_4)_3$ gave results in agreement with those obtained by Bodenstein and Pohl.

Action of steam on ferrous sulphide.

At an incipient red-heat steam decomposes ferrous sulphide with the formation of a black magnetic mass containing Fe_3O_4, and the evolution of hydrogen and hydrogen sulphide :—

$$3FeS + 4H_2O = Fe_3O_4 + 3H_2S + H_2.$$

At higher temperatures sulphur dioxide and sulphur are also products of the reaction.[11]

EXPERIMENTAL.

The first portion of the research consisted in determining the effect of various common gases and gas mixtures upon the desulphurisation of pyrites at different temperatures. The gases experimented with were air, air saturated with steam, steam, hydrogen, carbon monoxide, carbon dioxide, and coal gas.

Preparation of sample of pyrites.

A dozen or more lumps of pyrites, weighing approximately one pound, were pulverised and intimately mixed. This was used in the determination of the total sulphur in the pyrites, the result being 52·54%.

Measurement of temperature.

The temperature of the furnace in all experiments was determined by means of a platinum, platinum iridium thermo-couple, and a millivoltmeter.

Furnaces.

Two furnaces were employed, viz., for temperatures above 700° C. a gas-fired furnace designed for the determination of carbon in steels by the combustion method, and for lower temperatures an electric furnace. When both furnaces were heated the silica tubes passing through them were explored by means of the thermo-couple, and it was found that in the hottest zone of each furnace there was a length of 5–6 in. where there was no appreciable variation in temperature.

The apparatus.

A constant volume of the gas to be experimented with was passed over a known weight of pyrites heated to a determined temperature, and the percentage of residual sulphur in the mineral determined after treatment. The apparatus consisted of a gas holder, from which the gas was forced through a wash-bottle containing concentrated sulphuric acid to dry it, and then through the silica tube, which was contained in the furnace. Into the end of the tube near the sulphuric acid wash-bottle was inserted the thermo-couple, protected by a fireclay sheath, the end of which reached the hottest zone of the furnace. A fireclay boat, containing 5 g. of pyrites, was pushed in at the other end, until it touched the end of the thermo-junction. The combustion products passed finally through a wash-bottle containing sodium hydroxide solution to absorb SO_2, SO_3, and sulphur. The volume of air used was 17 litres for 5 g. of pyrites, when there was 0·85 litre of oxygen in excess of the amount theoretically required. The time taken for the whole 17 litres to pass through the furnace was two hours, and in all experiments this same rate of flow was attained.

In all experiments the pyrites was allowed to cool inside the furnace, so that it was not subject to the oxidising influences of the atmosphere.

Air.—After passing 17 litres of air over 5 g. of

Air and air saturated with steam.

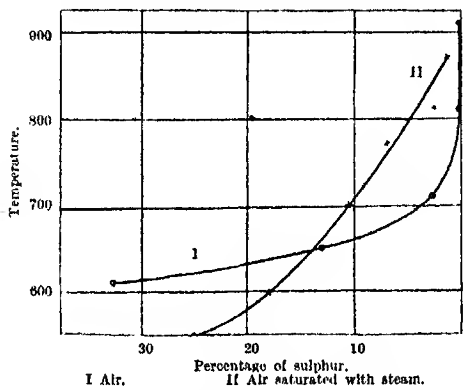

FIG. 1.

in pyrites, the sulphur content of the residual substance rapidly decreased from 32·99% at 610° C., to 13% at 810°, whilst at 910° the residual sulphur was only 0·092%. On plotting the results on a graph (Fig. 1) a perfectly smooth curve, not exhibiting any break, was obtained. The graph demonstrates that pyrites can be desulphurised almost completely under the conditions of the experiment, when heated to a temperature between 800° and 900° C.

Air saturated with steam.—The next set of experiments was carried out with air which before being passed over the pyrites was bubbled through boiling water. In order that all the experiments should be comparable the rate of ebullition was kept as nearly as possible constant. The results obtained are also plotted on Fig. 1. The curve shows that at temperatures below 650° C., air saturated with steam is more efficient as a desulphurising agent than dry air, whilst at temperatures above 650° the reverse is the case.

Steam.—In order to obtain a series of determinations showing the effect of steam as a desulphurising agent, the flask containing water was connected to a steam bath. Thus, by turning the tap of the steam bath, steam bubbled through the water in the flask, and then entered the silica tube. The wash-bottle containing sodium hydroxide solution was not used. Before the experiment was commenced the furnace was heated to the required constant temperature, while steam was passing through the silica tube,

Steam.

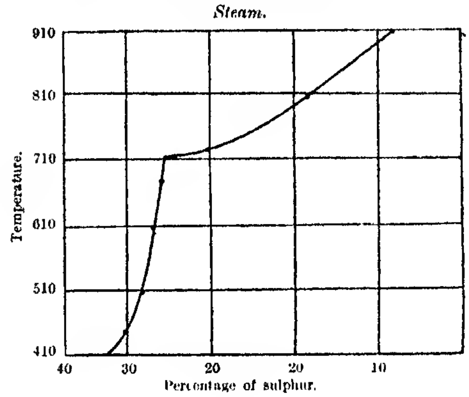

FIG. 2.

and then the fireclay boat containing the mineral was introduced. In order that approximately the same amount of steam should pass over each sample of pyrites, each experiment was of one hour's duration, and the rate of flow of steam through the apparatus was regulated by the height of the water in the tube open to the atmosphere, and dipping under the water in the flask. In every experiment the pyrites was allowed to cool inside the silica tube in an atmosphere of steam. It was then removed, and dried in a steam oven.

Although the results obtained in this manner are not strictly comparable with those obtained with other gases, they are useful when explaining the varying desulphurising action of air and air saturated with steam.

The graph obtained (Fig. 2) by plotting temperature against the percentage of residual sulphur indicates that desulphurisation commences at a temperature

in the region of 380° C., and increases rapidly as the temperature is raised to 500°. From 500° to 680° the amount of sulphur removed increases more gradually with rise in temperature, until at the latter temperature the sulphur content of the residue is 35·69%. Since the calculated percentage of sulphur in ferrous sulphide is 36·36, it is only reasonable to suppose that the action of steam on pyrites between 380° and 680° C. tends to produce ferrous sulphide:—

$$3FeS_2+2H_2O=3FeS+2H_2S+SO_2.$$

Water vapour is present in the system so that the hydrogen sulphide will reduce the sulphur dioxide with the separation of sulphur, thus:—

$$2H_2S+SO_2=2H_2O+3S.$$

The sulphur vapour is then swept away by more steam. The net result of the two reactions is the removal of one atom of sulphur from iron disulphide to form ferrous sulphide, while the quantity of steam at the end of the reactions is the same as that in the initial stages. Thus the steam appears to act as a catalyst of the dissociation of iron disulphide into ferrous sulphide and sulphur, which commences under ordinary conditions, according to E. T. Allen and R. H. Lombard, only at 575° C., and is complete in the vicinity of 700°.

About 700° the curve exhibits a marked break, and desulphurisation again rapidly increases with rise of temperature. At this temperature the iron disulphide will dissociate into ferrous sulphide and sulphur, the sulphur being carried away by the stream of steam. The steam will then react with the ferrous sulphide, according to the reaction advanced by Gautier:—

$$3FeS+4H_2O=Fe_3O_4+3H_2S+H_2,$$

which is stated to commence at incipient red heat; from the results obtained in these experiments this reaction begins at a temperature of 680° C.

Carbon dioxide.

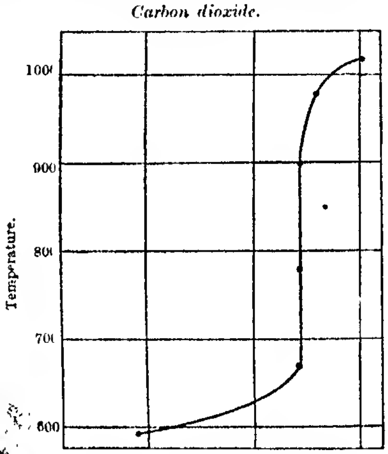

FIG. 3.

These reactions may be applied to the case of air and air saturated with steam, in order to explain the nature of the curves obtained in the experiments with these gas mixtures. Below 650° air saturated with steam removes more sulphur from pyrites than dry air.

Carbon dioxide.—Before the commencement of each experiment carbon dioxide was passed through the whole apparatus to remove all traces of air, and at the end of each experiment the boat containing the pyrites was allowed to cool in an atmosphere of the gas. The curve obtained by plotting the results (Fig. 3) shows that desulphurisation commences about 580°–590° C. As the temperature is raised to 670° the quantity of sulphur removed rapidly increases, until at this temperature the percentage of sulphur in the residue is 35·67, corresponding approximately to the formula of ferrous sulphide. Between 670° and 900° the residual sulphur content remains constant at 35·6%. Above 900° desulphurisation again increases, and at 1020° the residual sulphur is 29·88%.

Carbon monoxide.

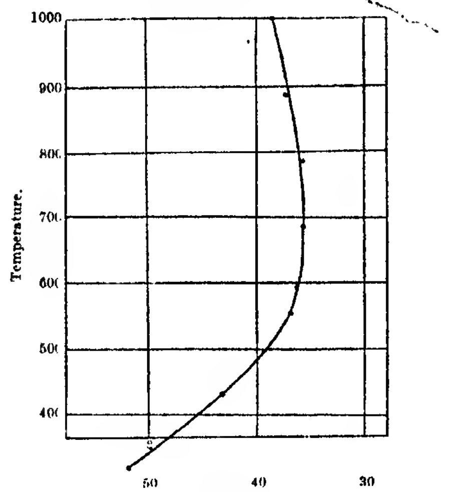

FIG. 4.

From these results it would appear that at temperatures below 900° C., carbon dioxide exerts no oxidising influence on the iron disulphide, but that this merely dissociates into ferrous sulphide and sulphur.

The action of carbon dioxide at temperatures above 900° C. may be explained as follows. At high temperatures carbon dioxide tends to dissociate; at 900° normally this reaction is unimportant. Raising the temperature, however, increases the decomposition, and if some oxidisable substance be present the whole of the carbon dioxide may, in time, be converted into carbon monoxide.

In the experiments performed an oxidisable substance in the form of ferrous sulphide is present. The carbon dioxide will then be decomposed into carbon monoxide and oxygen, the latter oxidising the ferrous sulphide.

Carbon monoxide.—The carbon monoxide used was prepared by passing carbon dioxide from the cylinder over heated charcoal. The gas was led through three wash-bottles, containing a concentrated

solution of caustic soda to remove any carbon dioxide, and collected in the gas holder. More carbon monoxide was collected in another gas holder, and this gas was used in expelling all air from the experimental apparatus before the commencement of each determination. The carbon monoxide was passed over 5 g. of iron pyrites in the same manner as before, and the residue in the fireclay boat was allowed to cool in the gas.

The graph (Fig. 4) obtained by plotting the percentage of sulphur against temperature shows that at 350° C. desulphurisation commences, and increases up to a temperature of 590°, where the composition of the residue corresponds to the formula of ferrous sulphide. Between 590° and 800° no further desulphurisation occurs, and above 800° the percentage of sulphur remaining gradually increases with rise in temperature from 35·56% to 38·25%.

At low temperatures carbon monoxide is very efficient in the removal of sulphur. Below 575° the iron disulphide does not dissociate, and the efficiency of the carbon monoxide is probably due to the combination of the gas with one atom of the sulphur in pyrites to form carbon oxysulphide :—

$$FeS_2+CO=FeS+COS,$$

since this gas is formed when a mixture of sulphur vapour and carbon monoxide is passed through a moderately-heated tube.

There is an increase in the amount of residual sulphur at temperatures above 800° C. At these temperatures a partial fusion of the sulphide on the surface may occur, which hinders the removal of more sulphur. This partial fusion of the sulphide is well known in the manufacture of sulphuric acid by the chamber process, and is always noticed in the pyrites burners, when they become overheated. The cinders after such treatment always contain more sulphur than cinders which have been properly burnt. This explanation of the increase in residual sulphur after treatment with carbon monoxide at high temperatures seems therefore to be correct.

Hydrogen.—The hydrogen used was obtained from cylinder of the gas, and the details of the experimental work did not differ in any respect from those using air.

The curve (Fig. 5) obtained indicates that hydrogen commences to remove sulphur from pyrites at a temperature of 440° C., and at 530° the iron disulphide totally converted into ferrous sulphide. The sulphur content of the residue then remains constant to 900° C., but between this temperature and 1000° there is a slight decrease in the percentage sulphur.

Between 440° and 575° the hydrogen reacts with the iron disulphide producing ferrous sulphide and hydrogen sulphide, according to the equation :—

$$FeS_2+H_2=FeS+H_2S.$$

At higher temperatures, since hydrogen sulphide begins to dissociate into its elements, the main factor which causes the removal of sulphur will be the dissociation of the iron disulphide. Above 900° C. the only reaction which will account for the decrease in the sulphur is the conversion of ferrous sulphide into metallic iron with the formation of hydrogen sulphide thus :—

$$FeS+H_2=Fe+H_2S.$$

Coal gas.—The experiments with coal gas were carried out in the same way as with the other gases.

Hydrogen and coal gas.

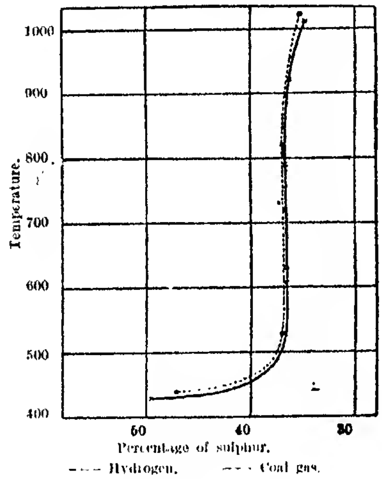

FIG. 5.

The curve (Fig. 5) obtained was practically the same as that of hydrogen.

Soluble sulphur determinations.

The weathering of ores containing sulphur, carried on in Sweden, converts some sulphide into sulphate, and the latter, being soluble in water, is washed away by the rain. It was, therefore, considered of interest to determine the amount of soluble sulphur in the pyrites after treatment with the various gases. The remaining portion of each sample of pyrites after the previous experiment was used.

The amount of soluble sulphur in the samples after treatment with air decreases with increasing temperature from 0·155% at 650° C. to 0·044% at 910°, while the sulphur determinations in the residue after treatment with air saturated with steam show a maximum of 0·227% at 600°. The soluble sulphur content of the samples treated with dry air was less than that of those treated in air saturated with steam for corresponding temperatures.

A series of experiments was then carried out with air at temperatures between 350° and 545°. Five grams of pyrites were placed in the furnace heated to a constant temperature, and air was passed over the sulphide without being dried. Each experiment was of three and a half hours' duration, the quantity of air passing through the furnace being approximately 30 litres per hour. The total sulphur and soluble sulphur were determined in the burnt pyrites, and these percentages were plotted against temperature.

No oxidation occurs below 330° C.; at 350° the soluble sulphur content is 2·72%, and this increases to a maximum of 4·05% at 430°, while a further

increase in temperature causes the percentage of soluble sulphur to decrease rapidly (Fig. 6).

The total sulphur curve (Fig. 7) shows a break at 430° C., corresponding to the maximum on the

Air.

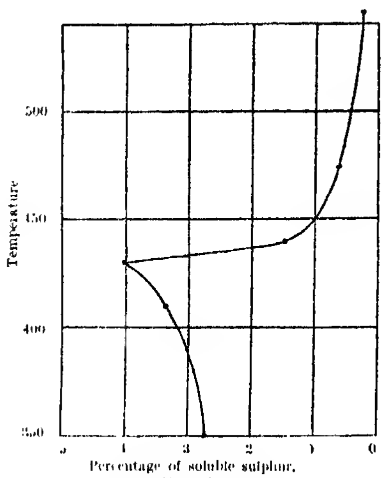

FIG. 6.

soluble sulphur curve. The first portion of these curves up to 430° corresponds to the formation of some soluble salt of iron containing sulphur, and the second portion to the decomposition of this salt.

The graph (Fig. 8) resulting from the soluble sulphur determination in the pyrites after treatment with steam, also reaches a maximum at 430° C., and

Air.

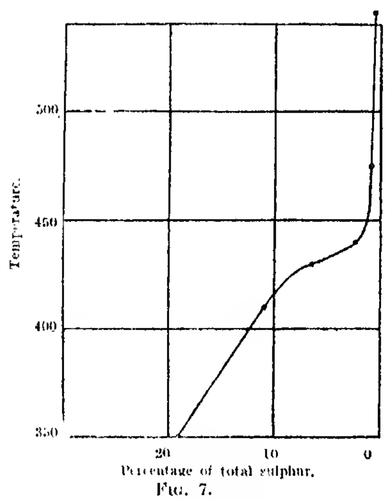

FIG. 7.

exhibits a break at 680° analogous to the break in the total sulphur curve.

The carbon monoxide and hydrogen soluble sulphur curves (Fig. 9) show maxima in the region of 530°–550° C., but the carbon dioxide and coal gas results present no striking feature. Since all the sulphides of iron are insoluble in water, it is difficult to explain the occurrence of a soluble iron-sulphur compound in the case of hydrogen and carbon monoxide, but its appearance is probably due to traces of moisture

Steam.

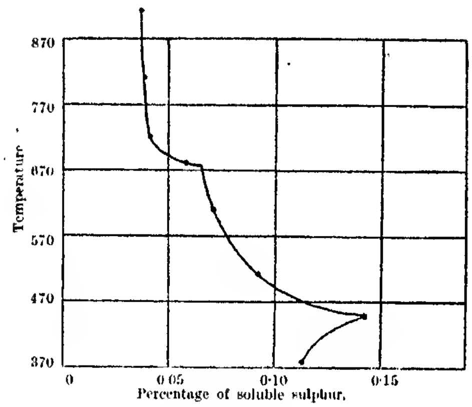

FIG. 8.

in the apparatus. This compound must be ferrous sulphate, since this salt begins to decompose at 530° C., and also the reducing conditions imposed by the gases will inhibit the formation of a ferric salt. The amount of soluble sulphur remaining after the action of hydrogen and those gases which convert the iron disulphide into ferrous sulphide, is greater than the amount obtained after the action of air and air saturated with steam. This is due to the conversion of part of the ferrous sulphide into ferrous sulphate and sulphuric acid during the digestion of the mass with water.

Carbon monoxide and hydrogen.

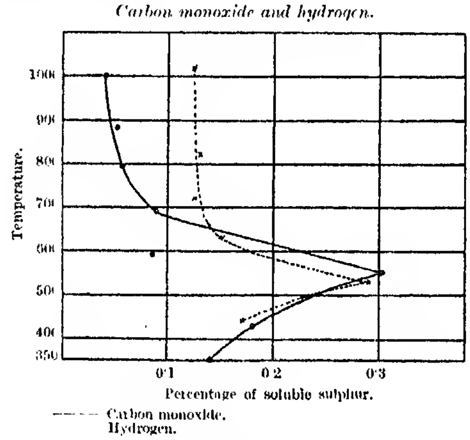

FIG. 9.

From these results it would appear that a soluble sulphur compound of iron may be an intermediate product in the oxidation of iron pyrites to iron oxide.

Up to this point a sulphate had been supposed to be the soluble iron salt. In order to ascertain the proportion of ferrous and ferric iron in the solutions,

obtained when the burnt pyrites was treated with water, the following determinations were made.

A sample of pyrites, after being heated for three-and-a-half hours at a constant temperature in the range of 400°–480° C., was weighed, and lixiviated with hot distilled water, and the solution obtained, after cooling, was made up to 250 c.c. in a graduated flask, and the amounts of ferrous and ferric iron and soluble sulphur were determined.

The results for the percentage of soluble sulphur, obtained indirectly from the weight of iron present in the solution, are not in agreement with those determined by the direct method of precipitation with barium chloride. In all cases where the pyrites was treated below 430° C., the sulphur derived from the iron determinations is always less than that obtained by the direct method, and in the great majority of those samples heated above 430° this is also true.

The cause of the discrepancy between the sulphur determined directly and that obtained indirectly, appears to go to the root of the removal of sulphur again. Further, the difference in the soluble sulphur as sulphates, and that present as a persulphate, is also at its maximum at 430° C., indicating that up to that temperature the persulphate is being formed, while as the temperature is raised still further it again breaks up.

Temperature, °C.	Ratio ferrous ferric.	Soluble S, %	Difference.*
370°	2 67	2 03	0 23
430°	1 41	3·39	1 11
480°	1 22	0 67	0·30

* Being % S determined directly *minus* that calculated from amounts of ferrous and ferric iron.

Determination of the vapour pressures of sulphur dioxide, sulphur trioxide, and oxygen during the oxidation of iron pyrites.

These determinations had a two-fold object: (1) to ascertain in what condition the sulphur was removed, (2) to ascertain whether the vapour pressures observed offer any data for the solution of the problem of the soluble sulphur.

The dynamic method was used, since it offers less experimental difficulties than the static method.

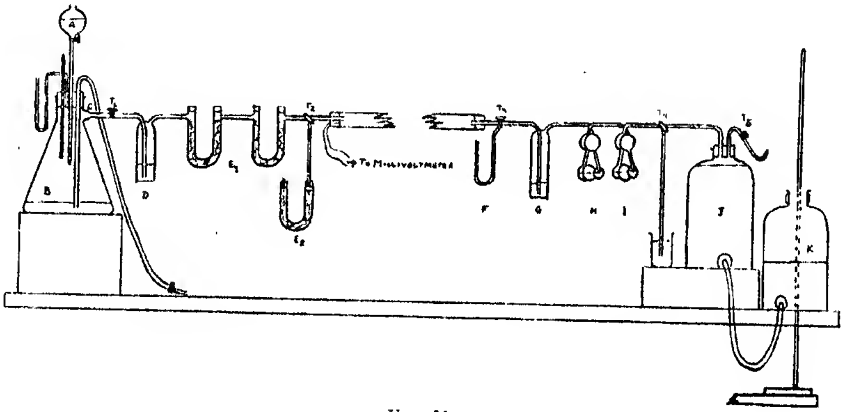

FIG. 10.

om a calcined ore by a process of weathering. In l probability there is formed some soluble sulphur mpound of iron which contains more sulphur than e sulphates, and exists along with the latter. On reful examination it was shown that the following sses of soluble iron compounds containing sulphur re absent: Acid sulphates, thiosulphates, sulphites, posulphites, and thionates, and that there was very ong reason to believe that a persulphate was sent. The existence of such a compound was er shown from the vapour pressure measurements, that it may be said with a tolerable degree of tainty, that a persulphate is the cause of the sence in the partly oxidised pyrites of a greater iount of soluble sulphur than is accounted for by e sulphates there. This persulphate is not improbably an intermediate product in the formation of the ferrous sulphate.

It will be seen from the figures below that as the temperature rises the ratio of the ferrous to the ferric iron decreases, that the amount of soluble sulphur increases to about 430° C., and then falls off

The apparatus was similar in construction to that used by Keppeler and D'Ans[9] in their determinations of the vapour pressures of sulphur dioxide and sulphur trioxide over dry sulphates of iron. A known volume of air was led over iron pyrites heated at a known temperature, and the amount of sulphur dioxide and sulphur trioxide determined by absorption, and the amount of oxygen by the analysis of the residual gas.

Fig. 10 represents the form of the apparatus finally employed. The Buchner flask, B, was fitted with a four-holed rubber stopper, provided with a dropping funnel, A, a thermometer, a pressure gauge containing xylene, and a glass tube reaching to the bottom of the flask. A long piece of rubber tubing, closed at the end by means of a screw clip, was fitted to this glass tube, so that water could be siphoned out of the flask when necessary. The side outlet tube, C, was connected through a tap, T_1, to a small wash bottle, D, containing concentrated sulphuric acid, and then to the U-tubes, E_1, containing calcium chloride, in order to dry the air used in the apparatus

ments. The last calcium chloride tube was connected to one end of the three-way tap, T_2, the second end of which fitted into the rubber stopper closing the end of the porcelain tube contained in the furnace, while to the third end a calcium chloride tube, E_2, was attached. At this end of the porcelain tube the thermo-couple was introduced, and its hot junction reached the hottest zone of the furnace. Inside the tube a fireclay boat containing about 5 g. of pyrites was placed, so that the end of the boat touched the end of the thermo-couple. The space at the opposite end of the tube was occupied by two fireclay boats containing pieces of broken fireclay. The end of the tube was closed by means of a one-holed rubber stopper, into which fitted one end of the three-way tap, T_3. The second end of the tap was connected to a pressure gauge, F, and the remaining end to the first absorption vessel, G, containing 40—50 c.c. of $N/20$ iodine solution. Then came two bulb tubes, H and I, the former containing more $N/20$ iodine solution, and the second 15 c.c. of $N/20$ sodium thiosulphate solution. The latter was attached to the three-way tap, T_4, to one end of which was connected a piece of glass tubing dipping under the surface of caustic soda solution contained in a beaker. The remaining end was connected to a bent glass tube, fitted into a two-holed rubber stopper, closing the open end of a glass bottle, J, so that it did not protrude beyond the end of the stopper into the bottle. Into the other boring of the stopper was fitted a bent capillary tube having a tap, T_5, and drawn out to a fine upturned point at the open end. The bottle had an outlet at the bottom which was connected by a long piece of pressure tubing to a similar outlet in the bottle, K. The latter could be raised or lowered when required. Both bottles contained a concentrated solution of caustic soda. All connexions were made with pressure tubing, and were rendered gas-tight by the use of collodion.

Experimental method.

On raising the bottles, K and J, the outlet tube up to T_4 and the whole of the capillary tube filled with the caustic soda solution. The pressure gauge, F, was then detached, and T_3 turned so that the absorption vessels were open to the air, while the porcelain tube was shut off from contact with the atmosphere. The absorption bulbs were connected to the beaker containing caustic soda solution, and carbon dioxide was passed through the absorption vessels to expel all traces of air, entering at T_3 and escaping through the liquid in the beaker under T_4. The passage of carbon dioxide was continued for a period of time, never less than half-an-hour, until, when the stream of gas was stopped, the caustic soda solution rapidly rose up the outlet tube from T_4. It was then assumed that all air had been expelled from the absorption apparatus, and the pressure gauge was replaced.

Meanwhile the furnace was being heated to the required constant temperature, the porcelain tube being connected to E_2, but not with E_1. T_1 was turned in order to shut off the flask from the drying train. A small quantity of water was placed in B, so that the siphon tube dipped below the surface of the liquid. A small quantity of water was then allowed to drop from the funnel into the flask, until the difference in the level of the xylene in the two limbs of the pressure gauge was about 7 cm. This was the pressure found to be necessary before air could be forced through the sulphuric acid drying bulb. The tap of the funnel was turned, and all water removed from the bulb by means of a pipette. 100 or 150 c.c. of distilled water were then placed in the funnel.

When the temperature of the furnace was steady at the required temperature, T_1 was opened, and the drying train connected with the porcelain tube, but not with E_2. Finally, the height of K was so adjusted that, on turning T_4 to connect the absorption vessels with the caustic soda bottles only, no caustic soda passed into the sodium thiosulphate bulb. Then the tap of the dropping funnel was turned, and water dripped slowly into the flask, forcing air into the apparatus. By raising or lowering the second caustic soda bottle it was so arranged that the height of the liquid in the two limbs of the pressure gauge, F, was the same throughout the experiment, and therefore the pressure inside the porcelain tube was atmospheric. When the water in the funnel had fallen to the tap it was turned off. T_1, T_2, and T_3 were then turned to their initial positions while T_4 remained unaltered. F was detached, and carbon dioxide again passed through the apparatus to drive all nitrogen and oxygen in the absorption bulbs into J. The carbon dioxide was readily absorbed by the caustic soda, and the passage of carbon dioxide was continued for half-an-hour or more. T_4 was then turned to allow the carbon dioxide to pass into the beaker containing caustic soda solution, and the stream of carbon dioxide was stopped.

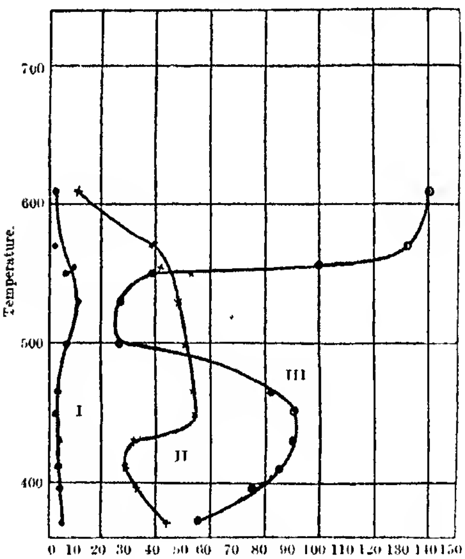
The sulphur dioxide and sulphur trioxide absorption tubes were then disconnected, and their contents emptied into a beaker. The excess of iodine was titrated with $N/20$ sodium thiosulphate solution, and hence the amount of iodine used in the reaction with sulphur dioxide was known. From this the weight of sulphur dioxide and finally the volume of sulphur dioxide at N.T.P. were calculated.

Keppeler and D'Ans determined the sulphur trioxide by titration of the residual solution with standard barium hydroxide solution. This method is, however, impracticable in the present case, since the solution is saturated with carbon dioxide. Hence the following method was adopted. Hydrochloric acid was added, and the solution boiled to decompose the sodium tetrathionate formed by the interaction of the iodine with sodium thiosulphate. Carbon dioxide was bubbled through the solution to facilitate the removal of sulphur dioxide, and after boiling for some time the sulphur was filtered off. The sulphate in solution was precipitated in the usual manner by the addition of barium chloride solution. Allowances were made for the sulphuric acid formed by the oxidation of sulphur dioxide by the iodine solution and the sodium sulphate formed by the decomposition of the sodium tetrathionate, and the weight and

hence the volume of sulphur trioxide at N.T.P. was calculated.

The amount of oxygen present was determined by absorption with alkaline pyrogallol. From the data thus obtained the volume of residual gas containing the amount of nitrogen in the original air could be calculated, and hence the volume of oxygen in the residue was known.

Sulphur [illegible]xide, sulphur trioxide, and oxygen pressures over heated iron pyrites during oxidation with air



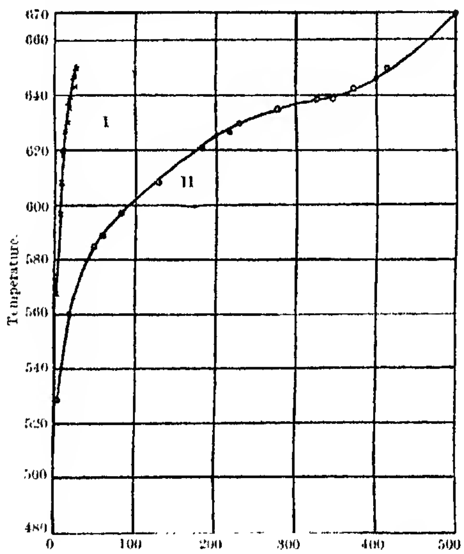
I Oxygen. II SO_3. III SO_2.

FIG. 11.

In order to test the accuracy of the apparatus the vapour pressures of sulphur dioxide and sulphur trioxide over dry ferric sulphate heated to a temperature of 670° C. were determined. The partial pressures of the two gases were then found to be $P_{SO_3} = 24·08$ mm. and $P_{SO_2} = 31·16$ mm. By reference to the graph of the vapour pressures of sulphur dioxide and sulphur trioxide over heated ferric sulphate obtained by Keppeler and D'Ans, the pressures of the two gases were observed to be 22 mm. and 33·5 mm., respectively. This agreement was sufficiently good for the determinations with iron pyrites, which were only performed in order to form an idea of the conditions in the gaseous phase during the oxidation of the sulphide. The ferric sulphate was then replaced by iron pyrites, and the ends of the porcelain tube were closed up. The same pyrites was used in all the determinations, and when it was removed from the furnace at the end of the series of experiments there was a comparatively large quantity of unchanged sulphide. The passage of air over the heated sulphide in each determination occupied between 70 and 80 minutes for 150 c.c. of air, and about 50 minutes for 100 c.c. The determined pressures of the three gases were plotted against temperature on a graph (Fig. 11).

The curves obtained by plotting the pressures against temperature were of a most extraordinary character. At 370° C. the vapour pressures of sulphur trioxide and sulphur dioxide are practically the same, but, as the temperature is raised, the partial pressure of the sulphur dioxide increases to 90 mm., while that of sulphur trioxide decreases to 28 mm. Between 430° and 450° there is a sudden increase in the amount of sulphur trioxide, while the sulphur dioxide remains constant. This increase is due to the decomposition of the soluble sulphur salt of iron. With further increase in temperature the sulphur trioxide gradually falls from 55 mm. at 450° to 39 mm. at 570° C. Meanwhile the sulphur dioxide pressure decreases rapidly to 25 mm. at 520°, and then again increases, until at 570° it is 130 mm. This increase corresponds to the decomposition of ferrous sulphate, since sulphur dioxide is the main constituent of the gaseous phase over the heated salt, and the dissociation of FeS_2, the sulphur vapour being oxidised to SO_2. At 610° C., the highest temperature at which a determination was made, the partial pressure of sulphur dioxide is 140 mm., while that of sulphur trioxide is 11 mm.

Sulphur dioxide and sulphur trioxide pressures over heated ferrous sulphate (Keppeler and D'Ans).



I Sulphur trioxide. II Sulphur dioxide.

FIG. 12.

The sulphur dioxide curve is perfectly continuous, although the vapour pressures are of such a varied nature, and all the points obtained find a position on it. The sulphur trioxide curve is flattened between 450° and 570° C., and the pressure obtained at 550° is too great to find a place on the smooth curve. It

ments. The last calcium chloride tube was connected to one end of the three-way tap, T_2, the second end of which fitted into the rubber stopper closing the end of the porcelain tube contained in the furnace, while to the third end a calcium chloride tube, E_2, was attached. At this end of the porcelain tube the thermo-couple was introduced, and its hot junction reached the hottest zone of the furnace. Inside the tube a fireclay boat containing about 5 g. of pyrites was placed, so that the end of the boat touched the end of the thermo-couple. The space at the opposite end of the tube was occupied by two fireclay boats containing pieces of broken fireclay. The end of the tube was closed by means of a one-holed rubber stopper, into which fitted one end of the three-way tap, T_3. The second end of the tap was connected to a pressure gauge, F, and the remaining end to the first absorption vessel, G, containing 40—50 c.c. of $N/20$ iodine solution. Then came two bulb tubes, H and I, the former containing more $N/20$ iodine solution, and the second 15 c.c. of $N/20$ sodium thiosulphate solution. The latter was attached to the three-way tap, T_4, to one end of which was connected a piece of glass tubing dipping under the surface of caustic soda solution contained in a beaker. The remaining end was connected to a bent glass tube, fitted into a two-holed rubber stopper, closing the open end of a glass bottle, J, so that it did not protrude beyond the end of the stopper into the bottle. Into the other boring of the stopper was fitted a bent capillary tube having a tap, T_5, and drawn out to a fine upturned point at the open end. The bottle had an outlet at the bottom which was connected by a long piece of pressure tubing to a similar outlet in the bottle, K. The latter could be raised or lowered when required. Both bottles contained a concentrated solution of caustic soda. All connexions were made with pressure tubing, and were rendered gas-tight by the use of collodion.

Experimental method.

On raising the bottles, K and J, the outlet tube up to T_4 and the whole of the capillary tube filled with the caustic soda solution. The pressure gauge, F, was then detached, and T_3 turned so that the absorption vessels were open to the air, while the porcelain tube was shut off from contact with the atmosphere. The absorption bulbs were connected to the beaker containing caustic soda solution, and carbon dioxide was passed through the absorption vessels to expel all traces of air, entering at T_3 and escaping through the liquid in the beaker under T_4. The passage of carbon dioxide was continued for a period of time, never less than half-an-hour, until, when the stream of gas was stopped, the caustic soda solution rapidly rose up the outlet tube from T_4. It was then assumed that all air had been expelled from the absorption apparatus, and the pressure gauge was replaced.

Meanwhile the furnace was being heated to the required constant temperature, the porcelain tube being connected to E_2, but not with E_1. T_1 was turned in order to shut off the flask from the drying train. A small quantity of water was placed in B, so that the siphon tube dipped below the surface of the liquid. A small quantity of water was then allowed to drop from the funnel into the flask, until the difference in the level of the xylene in the two limbs of the pressure gauge was about 7 cm. This was the pressure found to be necessary before air could be forced through the sulphuric acid drying bulb. The tap of the funnel was turned, and all water removed from the bulb by means of a pipette. 100 or 150 c.c. of distilled water were then placed in the funnel.

When the temperature of the furnace was steady at the required temperature, T_1 was opened, and the drying train connected with the porcelain tube, but not with E_2. Finally, the height of K was so adjusted that, on turning T_4 to connect the absorption vessels with the caustic soda bottles only, no caustic soda passed into the sodium thiosulphate bulb. Then the tap of the dropping funnel was turned, and water dripped slowly into the flask, forcing air into the apparatus. By raising or lowering the second caustic soda bottle it was so arranged that the height of the liquid in the two limbs of the pressure gauge, F, was the same throughout the experiment, and therefore the pressure inside the porcelain tube was atmospheric. When the water in the funnel had fallen to the tap it was turned off. T_1, T_2, and T_3 were then turned to their initial positions while T_4 remained unaltered. F was detached, and carbon dioxide again passed through the apparatus to drive all nitrogen and oxygen in the absorption bulbs into J. The carbon dioxide was readily absorbed by the caustic soda, and the passage of carbon dioxide was continued for half-an-hour or more. T_4 was then turned to allow the carbon dioxide to pass into the beaker containing caustic soda solution, and the stream of carbon dioxide was stopped.

The sulphur dioxide and sulphur trioxide absorption tubes were then disconnected, and their contents emptied into a beaker. The excess of iodine was titrated with $N/20$ sodium thiosulphate solution, and hence the amount of iodine used in the reaction with sulphur dioxide was known. From this the weight of sulphur dioxide and finally the volume of sulphur dioxide at N.T.P. were calculated.

Keppeler and D'Ans determined the sulphur trioxide by titration of the residual solution with standard barium hydroxide solution. This method is, however, impracticable in the present case, since the solution is saturated with carbon dioxide. Hence the following method was adopted. Hydrochloric acid was added, and the solution boiled to decompose the sodium tetrathionate formed by the interaction of the iodine with sodium thiosulphate. Carbon dioxide was bubbled through the solution to facilitate the removal of sulphur dioxide, and after boiling for some time the sulphur was filtered off. The sulphate in solution was precipitated in the usual manner by the addition of barium chloride solution. Allowances were made for the sulphuric acid formed by the oxidation of sulphur dioxide by the iodine solution and the sodium sulphate formed by the decomposition of the sodium tetrathionate, and the weight and

hence the volume of sulphur trioxide at N.T.P. was calculated.

The amount of oxygen present was determined by absorption with alkaline pyrogallol. From the data thus obtained the volume of residual gas containing the amount of nitrogen in the original air could be calculated, and hence the volume of oxygen in the residue was known.

Sulphur (xide, sulphur trioxide, and oxygen pressures over h. ated iron pyrites during oxidation with air

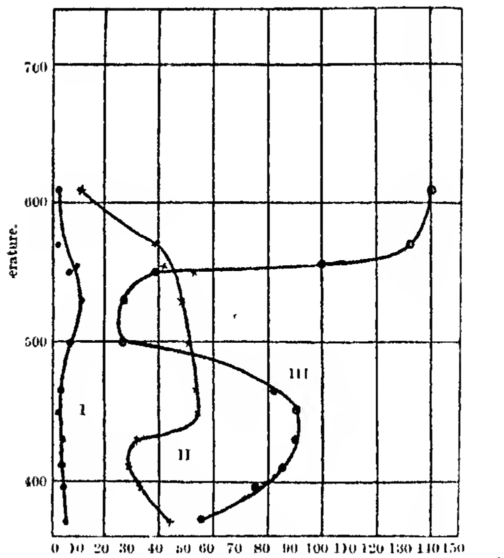


FIG. 11.

In order to test the accuracy of the apparatus the ıpour pressures of sulphur dioxide and sulphur ioxide over dry ferric sulphate heated to a temperare of 670° C. were determined. The partial essures of the two gases were then found to be $_{SO_2}$ = 24·08 mm. and P_{SO_3} = 31·16 mm. By referce to the graph of the vapour pressures of sulphur oxide and sulphur trioxide over heated ferric lphate obtained by Keppeler and D'Ans, the presres of the two gases were observed to be 22 mm. ıd 33·5 mm., respectively. This agreement was fficiently good for the determinations with iron rites, which were only performed in order to form ı idea of the conditions in the gaseous phase during e oxidation of the sulphide. The ferric sulphate as then replaced by iron pyrites, and the ends of e porcelain tube were closed up. The same pyrites was used in all the determinations, and when it was removed from the furnace at the end of the series of experiments there was a comparatively large quantity of unchanged sulphide. The passage of air over the heated sulphide in each determination occupied between 70 and 80 minutes for 150 c.c. of air, and about 50 minutes for 100 c.c. The determined pressures of the three gases were plotted against temperature on a graph (Fig. 11).

The curves obtained by plotting the pressures against temperature were of a most extraordinary character. At 370° C. the vapour pressures of sulphur trioxide and sulphur dioxide are practically the same, but, as the temperature is raised, the partial pressure of the sulphur dioxide increases to 90 mm., while that of sulphur trioxide decreases to 28 mm. Between 430° and 450° there is a sudden increase in the amount of sulphur trioxide, while the sulphur dioxide remains constant. This increase is due to the decomposition of the soluble sulphur salt of iron. With further increase in temperature the sulphur trioxide gradually falls from 55 mm. at 450° to 39 mm. at 570° C. Meanwhile the sulphur dioxide pressure decreases rapidly to 25 mm. at 520°, and then again increases, until at 570° it is 130 mm. This increase corresponds to the decomposition of ferrous sulphate, since sulphur dioxide is the main constituent of the gaseous phase over the heated salt, and the dissociation of FeS_2, the sulphur vapour being oxidised to SO_2. At 610° C., the highest temperature at which a determination was made, the partial pressure of sulphur dioxide is 140 mm., while that of sulphur trioxide is 11 mm.

Sulphur dioxide and sulphur trioxide pressures over heated ferrous sulphate (Keppeler and D'Ans).

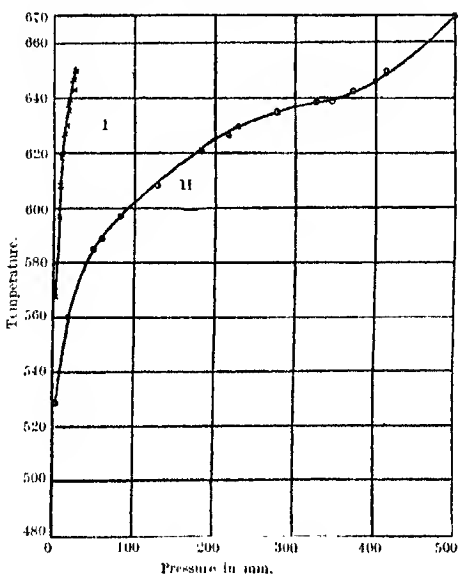

FIG. 12.

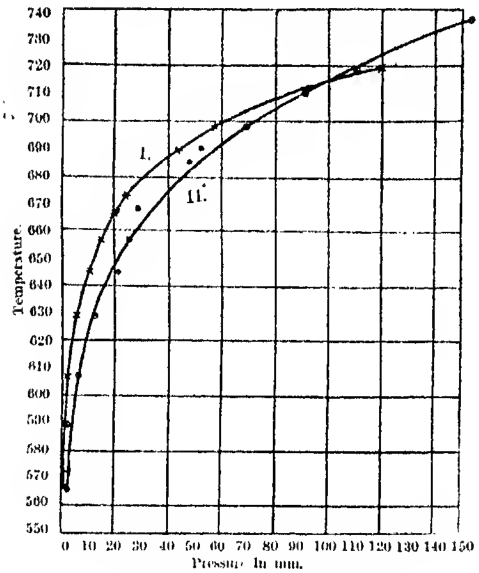
The sulphur dioxide curve is perfectly continuous, although the vapour pressures are of such a varied nature, and all the points obtained find a position on it. The sulphur trioxide curve is flattened between 450° and 570° C., and the pressure obtained at 550° is too great to find a place on the smooth curve. It

is noticeable that where this flattening occurs the sum of the pressure of the dioxide and trioxide is less than that at 370° C.

The following explanation appears to fit in well with the results. Even at 370° C. the low value for the oxygen pressure shows that the oxidation of the pyrites has already become appreciable, giving considerable vapour pressure for both the SO_3 and SO_2. As the temperature rises, the pressure of the former decreases. This would not be expected, but it fits in well with the idea of the formation of a persulphate from the ferric oxide already produced, and some of the SO_3. The increase of the pressure of the SO_2 would normally be expected. This formation of the persulphate continues to about 400° or just over, during which period there is a continuous decrease in the pressure of the SO_3. At that temperature the persulphate commences to decompose, as has already been shown from the soluble sulphate determinations. This decomposition of the persulphate generates sulphur trioxide, which rapidly increases in the gaseous phase.

Sulphur dioxide and sulphur trioxide pressures over heated ferric sulphate (Keppeler and D'Ans).



I. Sulphur dioxide. II. Sulphur trioxide.

FIG. 13.

At about 430° C. the fall in the vapour pressure of the SO_2 is the result of the formation of ferrous sulphate according to the equation :—

$$Fe_2O_3+SO_2+SO_3=2FeSO_4.$$

The simultaneous absorption of SO_3 flattens the curve for the vapour pressure of the latter, which would otherwise increase to a maximum at about 520° C.

At about 525° the ferrous sulphate commences to decompose; SO_2 and SO_3 are liberated, but in amounts which are widely different. Reference to Fig. 12 will show that the gaseous phase is almost entirely SO_2, the SO_3 having presumably decomposed according to the equation :—

$$2SO_3 \rightleftarrows 2SO_2+O_2.$$

The pressure of the SO_2 increases rapidly, while that of the SO_3 decreases. The oxygen produced will fail to increase the pressure of that element, as at these temperatures the pyrites is dissociating rapidly, and any oxygen generated will react with the sulphur vapour, producing more SO_2.

The only point of interest in the oxygen curve is the slight increase around 520° C., due to the decomposition of the persulphate, according to some such equation as :—

$$2FeS_2O_8 \rightleftarrows Fe_2O_3+SO_2+3SO_3+O_2.$$

Vol. XLIII., No. 10.] [March 7, 1924.

THE TENSILE STRENGTH OF RUBBER.

BY O. DE VRIES.

In the testing of crude rubber the determination of tensile strength has always taken a prominent place; many investigators determine only tensile strength and rate of cure, and nothing else; several manufacturers base their private valuation of the rubber mainly on the figures for tensile strength.

Now, rate of cure is a factor of chemical composition and not of quality in the strict sense of the word. Probably chemical analysis will never be able to eplace vulcanisation tests in the determination of the omplex of accelerators and retarding catalysts present n the rubber, and the vulcanising test will retain ts place as the surest and quickest means of deternining the amount of these catalysts. But this loes not promote the determination of rate of cure o the rank of a test of quality, and the fact remains hat at present in many cases, probably the majority, he quality of the crude rubber is only determined y means of one property, viz., tensile strength.

The breaking load of rubber is not actually so mportant a property as might appear from the ttention paid to it in testing work; rubber in ractice is seldom stretched to near the break. Even the tearability of rubber, for instance in tyrecovers, is not directly related to tensile strength determined by a regular, slow stretching process, nd is certainly more dependent upon the composiion of the mix than upon the properties of the crude ubber. There seems to be no other reason why nsile strength has been given so much attention an that other more suitable properties have not een formulated or have not yet been worked out fficiently.

It should further not be forgotten that breaking ures are always more or less accidental, and a tively large number of test pieces is necessary obtain a reliable average. The accurate deteration of tensile strength is a tedious process; ny of the published and unpublished figures have y little value, as the number of test pieces was too small and the error of determination far too ge to allow of any reliable conclusion being drawn. ere is little doubt that many consignments of ber have been condemned or accepted on insufient and unreliable figures by manufacturers who e their valuation on tensile strength determinations.

ur regular testing work led us to the conclusion at the tensile strength of first-grade plantation ıbber is practically always good and that, when ouble is experienced in manufacture, the reason is be sought amongst the other properties (rate of re, plasticity, etc.). For this reason, also, there is little inducement to determine this property. True, it is not always easy for manufacturers to know whether a certain lot of rubber is what producers call "first grade"; on certain markets the estate names are often replaced by dealer's marks, and a lot of native and Chinese smoked sheet is mixed under what is called "standard." In such cases the quality of the rubber must be carefully tested; but determinations of "slope" and viscosity are easier and give as good a verdict in such cases as tensile strength figures. In "off" grades and lower grades the figures for tensile strength are sometimes inferior; but in these grades pieces of dirt may play a rôle, and the quality of the rubber is much better gauged by properties such as slope and viscosity than by the (in such cases) doubly uncertain breaking figures.

There is, in our opinion, little doubt that in the future other testing methods will be developed, and that tensile strength determinations will be relegated to the fourth or fifth place or used only in special cases, for instance, in the study of new or deviating types of rubber with an uncommon content of serum substances, etc. Nowadays tensile figures are often used to determine "broadness of peak," the range of cures over which tensile strength is a maximum. This is certainly an important property for manufacturing purposes, but it is mainly influenced by the type of compound and not by the crude rubber, and it need not be expected to play a rôle in the routine testing of the ordinary forms of plantation rubber, though again its determination may be of value in the study of special types.

Relation between tensile strength and time of cure.

Whilst it will be generally acknowledged that tensile strength figures determined on separate samples are mostly unreliable (unless an excessive number of test pieces is used) and therefore should be accepted only with a certain reserve, there are pitfalls even when drawing conclusions from averages of a very large number of determinations, which have not received general attention. Many examples have been given, for instance, of the fact that quick-curing matured rubber (slab rubber etc.) gives rather high figures for tensile strength, and that smoked sheet gives higher figures than first quality crêpe; in this paper it is hoped to show that it would be unjustifiable to draw the conclusion that matured rubber is the best in quality, or that the quality of smoked sheet (as far as tensile properties are concerned) is better than that of crêpe.

1. *Estate samples.*—The largest number of figures is available when comparing data obtained in the regular testing of estate samples in the course of

years. For thin pale crêpe (" first latex ") our figures are summarised in Table I. :—

TABLE I.

Thin pale crêpe from estates.

Year.	Number of samples.	Tensile strength.	Standard time of cure	Slope.	Viscosity.
1917	265	1·385	119 ± 8·7	$35{\cdot}0^{5}$	34·5
1918	131	1·472	118 ± 6·0	35·5	31·0
1919	241	1·345	110 ± 8·4	36·0	27·2
1920	227	1·409	106 ± 7·0	34·7	30·5
1921	354	1·417	109·2 ± 7·3	34·6	35·5
1922	450	1·443	106·0 ± 6·8	35·2	32·7
	1668	1·403	110·5	$35{\cdot}2^{5}$	32·3

The figures for tensile strength variations which, at least to a great extent, must be ascribed to experimental errors, mostly fall under the head, " errors of the testing machine " (the smoothness of running decreases as the axles and ball bearings become slightly worn etc.). These errors make it difficult to compare figures over a long range of years, but are without importance for the purpose of this discussion, as the difference between crêpe and smoked sheet in each year, and the average of these differences over a period of six years, are independent of these errors.

Incidentally it may be pointed out that the figures for standard time of cure show a gradual decrease from about 119 to about 107 minutes. This is principally caused by the fact that estates have gradually abandoned the old practice of diluting the latex to 15% rubber content for crêpe preparation and have changed over to a standard dilution of of 20 or 25%.

The figures for slope and viscosity are added for the sake of completeness, but are not of interest for the present purpose and will not be discussed here.

In the same way the average figures for smoked sheet were :—

TABLE II.

Smoked sheet from estates.

Year	Number of samples.	Tensile strength.	Standard time of cure	Slope	Viscosity.
1917	295	1·405	99 ± 9·8	37·2	35·1
1918	193	1·377	95 ± 10·2	36·5	31·5
1919	334	1·370	95 ± 10·4	36·4	28·3
1920	234	1·408	93 ± 11·9	35·6	32·1
1921	272	1·436	96·9 ± 13·6	35·7	35·8
1922	319	1·415	108·7 ± 11·8	37·3	33·4
	1647	1·407	97·7	36·4	32·6

For tensile strength the same remarks hold as for crêpe. The rate of cure of smoked sheet shows an increase in the last few years, and more and more approaches that of thin pale crêpe. The principal causes are : more soaking in water to decrease the liability to mouldiness, and quicker drying in better-equipped smoke houses.

The six years' averages indicate for smoked sheet a slightly higher tensile strength (1·407 as compared with 1·403, therefore only a difference of 0·004 kg. per sq. mm.) combined with a 12·8 minutes' shorter cure. The conclusion that the tensile strength for both types of rubber is the same, independent of rate of cure, would, however, be incorrect. The samples originate from different estates and therefore from different lots of latex ; and the result may be influenced by factors such as the fact that in later years the younger estates have for the greater part started preparation in the form of smoked sheet. The samples of smoked sheet, therefore, may contain more rubber from relatively young trees, res[illegible] slightly lower tensile strength and quicker c[illegible]

Though, therefore, the large number of s[illegible]s reduces the errors of determination to a minimum, the nature of the samples renders the above figures unsuitable for strict theoretical conclusions.

Crêpe and sheet from the same latex.—To find the real difference it is necessary to compare samples of crêpe and sheet prepared from the same latex. Different experiments made in the course of years gave :—

TABLE III.

Experiment.	Crêpe Tensile strength	Crêpe Time of cure.	Sheet. Tensile strength.	Sheet. Time of cure.	Difference in tensile strength per 10 minutes
I.	1·42	96	1·43	88	0·013
II.	1·39	121	1·43	90	0·013
III.–VI.	1·36	106	1·378	80	0·007
VII	1·38	98·8	1·418	77·2	0·017
VIII	$1{\cdot}40^{5}$	115	$1{\cdot}42^{5}$	83^{5}	0·006
IX	1·42	105	1·47	83	0·023
	1·396	$106{\cdot}0^{5}$	1·425	83·6	0·013

Experiments III.–VI. relate to crêpe and unsmoked sheet prepared in the laboratory, the others to crêpe and smoked sheet prepared on estates.

It will be seen that the tensile strength for smoked sheet is always higher than for crêpe. The figures in the last column differ rather widely for the different experiments, the number of determinations in each case having been relatively small. The average difference (0·013 kg. per sq. mm.) coincides with the average obtained in the experiments to be discussed later.

Special experiments.—The foregoing experiments confirm the conclusion that the quicker curing sheet rubber shows a somewhat higher tensile strength than the slower curing crêpe. They allow of *no* conclusion as to the cause of this difference, which might be due to treatment of the rubber (crêpeing against sheeting), to the form of the rubber (larger relative surface of crêpe), or to longer heating during vulcanisation because of the difference in time of cure.

To decide this point special experiments were made, a series of crêpes and sheets (unsmoked) being prepared from the same latex in such a way that for each type different times of cure were obtained. Crêpes with a shorter time of cure than usual were obtained by keeping the coagulum for 24, 48, or 72 hours before crêpeing, so that a beginning of maturation set in : sheets with a longer time of cure than usual were obtained by soaking for 2 or 5 hours in water after milling, so that part of the serum substances was removed. It is, of course, extremely improbable that such simple operations as keeping the unmilled coagulum, or soaking the freshly rolled sheets in water, affect the rubber and alter its tensile strength.

A first series of four experiments gave the figures in Table IV., where the " quick curing " and the

'slow curing" samples of each type are taken ogether.

TABLE IV.

Averages from series 1697, 1710, 1735, *and* 1746.

Description.	Number of samples.	Tensile strength.	Time of cure.	Slope.	Viscosity.
Crêpe, quick curing	6	1·467	86·7	36·0	36·5
Sheet, ,, ,,	8	1·433	83·7^{5}	36·9	39·2
Crêpe, slow ,,	7	1·404	112	37·3	34·0
Sheet, ,, ,,	5	1·44	111	37·1^{5}	34·4

In the quick-curing group the tensile strength of he crêpes is higher, and in the slow-curing group the sheets show a better tensile strength. The figures are plotted in the accompanying figure and will be discussed later.

In a second series of experiments two coagula were prepared for crêpe and one for sheet on five consecutive days; one of the coagula for crêpe preparation was milled on the day after coagulation, and the other was taken from the serum and left on a board to mature for three days. The coagulum for sheet preparation was milled a few hours after coagulation. From each series the figures were taken either of one crêpe showing about the same time of cure as the sheet, or of the two crêpes, so that their average time of cure nearly corresponded with that of the sheet.

The result was :—

TABLE V.

Averages from five experiments (*Series Nos.* 1762 *and* 1779).

Description.	Tensile strength.	Time of cure.	Slope.	Viscosity.
Crêpe	1·43	81	36·8^{5}	38·5
Sheet	1·44	82^{5}	37·7	39·7

The average time of cure and the average tensile strength are very nearly the same, but the slightly quicker curing crêpe shows a slightly lower, and not a slightly higher tensile strength.

A third and more extensive experiment was therefore made in the same manner as the first one, one series being prepared from undiluted latex and one from 15% of latex, and each repeated four times.

The figures are given in Table VI. :—

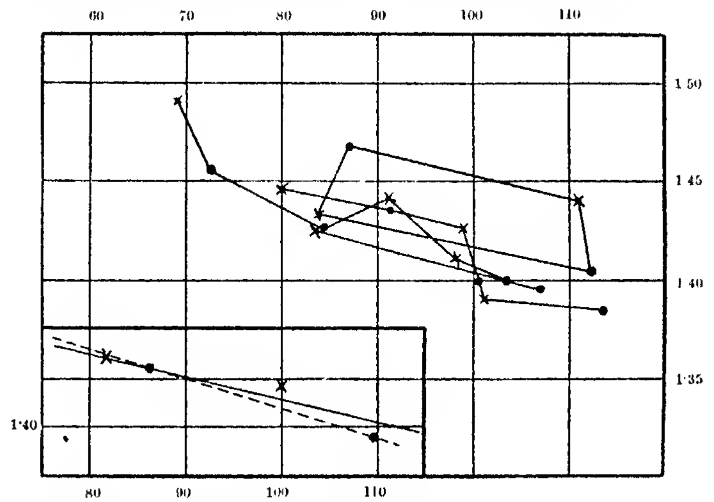
TABLE VI.

Averages from series 2279, 2299, 2285, *and* 2304.

Description.	Undiluted latex: Tensile strength.	Time of cure.	Slope.	Viscosity.	15% latex: Tensile strength.	Time of cure.	Slope.	Viscosity.
Crêpe, rolled same day	1·40	103^{5}	37·2	23·9	1·38^{5}	113^{5}	37·7	25·4
,, ,, next day	1·42^{5}	84^{5}	36·7	27·2	1·40	100^{5}	38·0	23·6
,, ,, after 3 days	1·47^{5}	72^{5}	37·1	29·7	1·43^{5}	91^{5}	37·1	26·6
Sheet, rolled next day	1·49	69	37·8	28·6	1·44^{5}	80	36·9	31·0
,, soaked 1 hour in water	1·44	91	36·4	25·3	1·39	101	38·3	26·3
,, soaked 5 hours in water	1·41	98	36·5	24·3	1·42^{5}	99	38·3	25·7

The figures for tensile strength and time of cure are plotted in the figure; though they do not lie on a straight line, it will be seen that there is no question of the crosses (sheets) always lying higher than the points (crêpe).

Summarising the results from Tables III.—VI., the average crêpes below and above 100 minutes and of sheets below and above 90 minutes furnish the following figures :—



Tensile strength at standard state of cure, plotted against standard time of cure (see Tables III., IV., and VI.). Inset, average figures (see Table VII.).

FIG. 1.

TABLE VII.

Description.	Number of cases.	Tensile strength.	Time of cure.
Crêpe, below 100 minutes	7	1·430^{5}	85·9
Crêpe, above 100 minutes	8	1·395^{5}	109·6
Sheet, below 90 minutes	10	1·431^{5}	81·7
Sheet, above 90 minutes	5	1·421	100·0

These figures are reproduced in the figure (inset); three points lie on a straight line (dotted line) with a slope of 0·014, the fourth lies slightly higher. The slope for the average line (straight line) is 0·012 kg. per sq. mm. for 10 minutes.

The conclusions therefore are :—

(1) The figures for tensile strength are affected by the duration of the cure ; in the testing method employed, an increase of 10 minutes in time of cure causes a decrease of about 0·012—0·014 kg. per sq. mm. in tensile strength.

(2) Sheet and crêpe, prepared from the same latex, have the same tensile strength when the above correction for difference in time of cure is taken into account.

With the aid of the above some special cases will now be discussed.

Rubber from young trees.

Young trees, not yet large enough to be taken into the tapping round, give a rather quick curing rubber with a low tensile strength, a low viscosity, and a high figure for slope, therefore of decidedly inferior quality. In different experiments sheet and crêpe from young trees have been compared and the following results found :—

TABLE VIII.

XI.	1·29	82	1·34	58	0·021
XII.	1·38	97	1·45	64	0·021
XIII.	1·22	53	1·29	44	0·08
XIV.	1·26	77	1·32*	58	0·04
XV.	1·37	96	1·44*	68	0·021

The first three (X.—XII.) relate to one group of trees at the age of 3, 4½, and 7½ years. The difference in tensile strength between crêpe and smoked sheet for 10 minutes' difference in time of cure is, on the average, 0·020 kg. per sq. mm., therefore somewhat higher than the general average mentioned above. Plotting the points in the above figure, the first two experiments give lines with about the same slope as the others, but lying much lower on the paper, which shows that the tensile strength of this type of rubber is really inferior.

The last two experiments (XIV. and XV.) also relate to one group of trees at the age of 4½ and 8 years ; these experiments give a rather high figure for "difference," but the inferiority of tensile strength at the age of 4 years is again evident.

Experiment XIII. gives the highest figure, viz. 0·08 for the "difference," but this rubber was very quick curing : in this case a difference of 10 minutes is about 20% of the time of cure, instead of 10% as with ordinary rubber, and the correction-factor for quick-curing rubber would have to be determined separately.

Matured rubber.

It is well known that matured rubber vulcanises quickly and gives a slightly higher figure for tensile strength. It was necessary to ascertain what remains of this excess tensile strength when the correction for time of cure is taken into account. Table IX. summarises the results :—

TABLE IX.

Experiments.	Matured rubber Tensile strength.	Matured rubber Time of cure.	Ordinary crêpe. Tensile strength.	Ordinary crêpe. Time of cure	Difference for 10 minutes.
XVI.	1·37	91	1·36	139	0·002
XVII.	1·44	75	1·40	127	0·008
XVIII.	1·41	50	1·37	116	0·006
XIX.	1·41	75	1·37	116	0·01
XX.	1·474	28·2	1·443	106·9	0·004
XXI.	1·49*	40·3	1·40	113¼	0·013

Of these figures only those in experiments XVI. and XVII. relate to ordinary crêpe and crêpe from matured rubber, prepared from the same latex. Experiment XXI. comes very near to this condition, as it relates to slab rubber prepared on an estate over a period of five months, and to crêpe prepared on the same estate on other days or from another part of the latex. In the other experiments the average figures for ordinary crêpe for the same year have been used for the comparison.

It will be seen that the excess tensile strength of matured rubber is in two cases (exp. XIX. and XXI.) about equal to what might be expected ; in the other cases it is smaller than that calculated from the difference in time of cure, using the average figure of 0·012 kg. per 10 minutes. Of course, the correction figure for small times of cure such as 28 or 50 minutes may perhaps differ from the average correction factor found for times cure of from 70 to 110 minutes ; but if any conclusion is allowable from the above table it would be that the tensile strength of matured rubber, corrected for time of cure, is lower and decidedly not higher than that of ordinary rubber. To claim a superior quality for matured rubber from the tensile figures is, to say the least, premature.

Coagulation with alum and sulphuric acid.

Coagulants such as alum and sulphuric acid, when used in rather large amounts, produce a slow-curing rubber with a lower tensile strength than usual. As examples the following may be mentioned* :—

TABLE X.

Coagulant used.	Tensile strength.	Time of cure.	Ordinary crêpe. Tensile strength.	Ordinary crêpe. Time of cure.	Difference for 10 minutes.
Alum	1·33	210	1·42	85	0·008
	1·43	150	1·46	115	0·008
	1·43	202	1·48	115	0·003
	1·32	220	1,46	115	0·013
	1·30	101	1·42	110	0·004
Sulphuric acid	1·33	135	1·38	107	0·018
	1·39	106	1·42	92	0·021
	1·38	115	1·42	98	0·024
	1·27	116	1·36	98	0·05
	1·10	220	1·45	82	0·025
Hydrochloric acid	1·28	180	1·45	82	0·017
Crater water	0·98	208	1·35	115	0·04
	1·12	150	1·35	115	0·07
	1·0	235	1·35	115	0·08
	1·37	107	1·40	118	0·006

It will be seen that in the case of alum the decrease in tensile strength is less than might be expected from the increase in time of cure. The supposed deterioration of the rubber by alum is therefore not confirmed by these results ; it is hoped shortly to publish other proofs that alum leaves the real quality of the rubber unharmed, although it gives the rubber an abnormally low rate of cure.

Hydrochloric acid also, when used in excess, seems (from the one experiment mentioned above) to cause no decided deterioration ; as a coagulant, however, this acid is quite unsuitable (as is well known) as it causes the rubber to become tacky.

Sulphuric acid, used in large excess (a[illegible] or so[illegible] experiments mentioned in Table X.), caus[illegible] the [illegible] a deterioration, the decrease in tensile str[illegible]ength in all cases larger than calculated from [illegible]ents [illegible] the [illegible]ck curi[illegible]

* See Arch. v. d. Rubbercultuur, 1920, 4, 210.

correction-factor of 0·012. The influence of crater water (containing alum, sulphuric and hydrochloric acids) is still more deleterious.

Results obtained by other investigators.

The difference in tensile strength caused by a difference in time of cure may be found also in the results of other investigators, but the correction factor seems to be dependent upon the method of testing.

As average figures B. J. Eaton and co-workers† mention :—

Description.	Tensile strength.	Time of cure.	Difference for 10 minutes.
Slab rubber	1·51	75	0·006
Smoked sheet	1·46	165	0·053
Crêpe	1·30	195	

For the rather long cures necessary in this testing method (10% sulphur, 140°) the difference in tensile strength for 10 minutes between smoked sheet and crêpe seems to be much larger than in the present case, viz., 0·053 insread of 0·012; the figure would even be twice as large if 10% of the time of cure were taken instead of 10 minutes, which is in this case only 5% of the time of cure. The excess tensile strength of slab rubber is, as in the present case, smaller than that calculated from the difference between smoked sheet and crêpe.

Special cases.

In the course of years several complaints have been received from manufacturers about inferiority in tensile strength of rubber from estates which were known as good ones. In two cases samples were obtained from the rejected lots; the results obtained in testing these were compared with the figures obtained in the regular testing of samples from the estate in question, and gave the following :—

TABLE XI.

Case.	Description.	Tensile strength.	Time of cure.	Slope.	Viscosity.
I.	Rejected lot	1·40*	72	37½	35
	Ordinary figures	1·45	105	37	34
	,, ,,	1·43	95	38	44
II.	Rejected lot	1·30	120	35½	29
	Ordinary figures	1·42	>95	37	35
	,, ,,	1·45	115	36½	34

In the first case the sample (unsmoked sheet), which was sent to us by the manufacturer, got wet in transport and evidently matured to some extent; nevertheless the figure for tensile strength in our testing is quite good. In the second case (smoked sheet) the figure for tensile strength is also quite good, considering that the "rejected" rubber was more than a year old when tested. An explanation of the low figures found by the manufacturer's chemists could not be given; probably some of the many sources of error which make tensile strength determinations so tedious have been at play.

The above and similar cases raise the question as to the influence of the sea voyage on the properties of rubber. A deterioration—mostly called oxidation—of crêpe rubber on keeping is postulated by many authors. The present author has shown‡ that, when kept in the tropics, first quality plantation rubber does not show a deterioration or decrease in tensile strength even in the course of 3—4 years; the following figures show that crêpe rubber, during a voyage to Europe or America and back to the East, does not deteriorate to any marked degree. The samples were used for comparative testing experiments and were sent to different investigators, who, after making their tests on part of the sample, sent back the rest for a control test. The figures obtained on the part of the samples kept at Buitenzorg and on the parts sent to Europe or America and back are given in Table XII. :—

TABLE XII.

Experiment.	Description.	Tested.	Tensile strength	Time of cure.	Slope.	Viscosity.
XXII.	Original sample	Dec., 1916	1·45	130	36	43
	Same, kept in C.R.S.	March, 1917	1·42	135	36	—
	Same, to England and back	June, 1917	1·34	125	35½	44
	Same, kept in C.R.S.	June, 1917	1·37	125	35½	46
	Same, kept in C.R.S.	Nov., 1917	1·38	130		—
XXIII.	Original sample	June, 1920	1·30	115	37	20½
	To England and back	July, 1620	1·52	115	36½	22
	To America and back	July, 1920	1·31	120	36½	21
	Kept in C.R.S.	July, 1920	1·44*	115	36½	19½

In the first case the sample sent to England and back showed a slight decrease in tensile strength, compared with the sample kept at Buitenzorg, and this difference occurred regularly in all the comparative tests made in June, 1917 (of which the average figures only are mentioned in Table XII.). The sea voyage therefore seems to have had a decided, though small, deteriorating effect on the tensile strength; the other properties remained unchanged.

In the second case (experiment XXIII.) the results do not agree so well. The sample sent to America showed a low figure for tensile strength after its return, but the part that had travelled to England gave a very high figure; the average of these two figures of 1·41 is exactly the same as the average of the two figures for the part kept at Buitenzorg. It may be assumed that the high and low figures for tensile strength must be ascribed to experimental errors, especially so as the viscosity remained practically unchanged; it is evident that the figures do not point to a decided decrease in tensile strength or in the other properties caused by the sea voyage.

CONCLUSIONS.

The figures for tensile strength are influenced by the length of time that the rubber is heated during vulcanisation. An increase in time of cure of 10 minutes (about 10%) gave a decrease in tensile strength of about 0·012—0·014 kg. per sq. mm. (about 1%).

Taking into account this correction, the tensile strength for (quicker curing) sheet and (slower curing) crêpe from the same latex is found to be the same, so that there is no real superiority of smoked sheet over first quality crêpe in this respect.

Slab rubber (quick-curing matured rubber), after applying this correction, does not show a higher tensile strength than sheet or crêpe, and there is no reason to call it superior in this respect.

† Bull. No. 27, Dept. of Agric. F.M.S.
‡ Arch. v. d. Rubbercultuur, 1921, 5, 140.

Rubber coagulated with alum, despite its very long time of cure, does not show a deterioration in (corrected) tensile strength, and this property is not affected by the use of alum as a coagulant. Sulphuric acid, used in excess, seems to cause a larger decrease in tensile strength than corresponds with the increased time of cure.

Special experiments did not point with certainty to a deteriorating influence of the sea voyage on the tensile strength of crêpe rubber.

Central Rubber Station,
Buitenzorg, Java.

THEORY OF ABSORPTION TOWERS.—A CORRECTION.

BY J. R. PARTINGTON, D.SC., AND L. H. PARKER, D.SC.

An error in the second calculation in our paper, "The Theory of Absorption Towers for Nitric Acid Manufacture" (J., 1919, 75 T), has kindly been pointed out to us by Mr. J. W. McDavid, whose corrected calculation we give below.

In the calculation it was shown that 1·125 lb. of water per minute were necessary to produce 100% nitric acid from the given stream of NO_2. The weight of 100% acid produced $= \frac{63}{9} \times 1{\cdot}125 = 7{\cdot}875$ lb., and to convert this to 50% acid a further 7·875 lb. are required. Hence the total water per min. $= 7{\cdot}875 + 1{\cdot}125 = 9{\cdot}00$ lb.

The actual water of dilution of this acid is 7·875 lb. and the weight of the acid leaving the first tower is the whole of the acid produced. The latter is obtained by converting 90% of the total weight of NO_2 to 50% nitric acid as follows:—

$$\frac{63}{46} \times \frac{10}{5} \times \frac{9}{10} \times 500 \times 0{\cdot}0128 = 15{\cdot}78 \text{ lb.}$$

Similarly if x = weight of HNO_3 entering first tower, the water used up in producing this acid is $x/7$. The water of dilution is therefore $9 - x/7$, and since the ratio $HNO_3 : H_2O = 3 : 7$, we have:—

$$\frac{x}{9 - x/7} = \frac{3}{7}$$

or $x = 3{\cdot}64$ lb. and $9 - x/7 = 8{\cdot}50$. Hence the weight of acid entering the first tower is $3{\cdot}64 + 8{\cdot}50 = 12{\cdot}14$ lb. The absorption in the first tower is therefore $7{\cdot}89 - 3{\cdot}64 = 4{\cdot}25$ lb. $HNO_3 = 3{\cdot}1$ lb. NO_2 per min. The concentration of the gas leaving the first tower is thus 5·15%, and hence the volume of the first tower is 343 cub. ft., and the total volume of the remaining towers, 867 cub. ft.

Mr. McDavid has also given an alternative method of calculation in which the nitric acid solutions are regarded as made up of N_2O_5 and H_2O. A 50% HNO_3 solution, for example, contains 42·86% of N_2O_5 and a 30% solution, 25·714% of N_2O_5.

In the problem under consideration, the total water present in each case is 9 lb. In a 50% HNO_3 solution 9 lb. are equivalent to 57·14% of the total weight, and therefore the weight of N_2O_5

$$= \frac{42{\cdot}86}{57{\cdot}14} \times 9 \text{ lb.} = 6{\cdot}75 \text{ lb. of } N_2O_5 = 7{\cdot}88 \text{ lb. of } HNO_3 = 15{\cdot}76 \text{ lb. of } 50\%\ HNO_3.$$

In a 30% nitric acid solution 9 lb. of H_2O are equivalent to 74·286% of the weight, and therefore the weight of N_2O_5

$$= \frac{25{\cdot}714}{74{\cdot}286} \times 9 \text{ lb.} = 3{\cdot}12 \text{ lb. } N_2O_5 = 3{\cdot}64\ HNO_3 = 12{\cdot}13 \text{ lb. } 30\%\ HNO_3.$$

Hence the weight of N_2O_5 absorbed in the first tower $= (6{\cdot}75 - 3{\cdot}12) = 3{\cdot}63$ lb. of $N_2O_5 = 3{\cdot}1$ lb. of $NO_2 = 4{\cdot}24$ lb. of HNO_3.

The concentration of gas leaving the first tower is therefore

$$\frac{6{\cdot}4 - 3{\cdot}1}{6{\cdot}4} \times 10 = 5{\cdot}15\%\ NO_2.$$

$$\therefore \log. \frac{10}{5{\cdot}15} = \frac{42 \times V}{50{,}000}$$

i.e., $V = 343$ cub. ft.

JOURNAL of THE SOCIETY OF CHEMICAL INDUSTRY

Vol. XLIII., No. 11.] TRANSACTIONS [March 14, 1924.

KINETICS OF HYDROGENATION.*

BY E. J. LUSH, M.A., A.I.C.

In a previous communication† the author described a new process of hydrogenation of oils in which use was made of nickel turnings activated by being anodically oxidised and afterwards reduced in hydrogen in a suitable vessel; oil was hydrogenated by allowing it to flow over the catalyst thus produced in an atmosphere of hydrogen.

Drip method—186°—201° C.

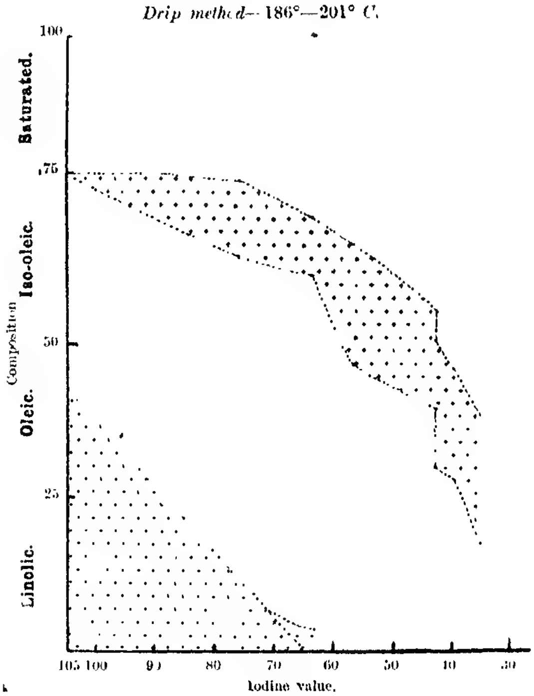

FIG. 1.

It was shown by graphs that the course of hydro-·nation, more particularly the formation of iso-leic acid, varied according to the mode of operation described respectively as the "drip" and "over-ow" methods. It was suggested that this difference ave support to the views of Moore‡ that the iso-leic acid resulted from the dehydrogenation of ewly-formed stearic acid.

The formation of iso-oleic acid has been further ivestigated, more especially with regard to the fect of temperature and pressure.

Figs. 1 and 2 show the effect of hydrogenation of otton oil at 190° and 150° C. respectively. At the higher temperature it will be seen that a greater amount of iso-oleic acid is formed, but that no increase in saturated acids occurs until the iodine value falls below 75. At 150° C. for the same drop in linolic acid there is less iso-oleic acid produced

Drip method · 150° C.

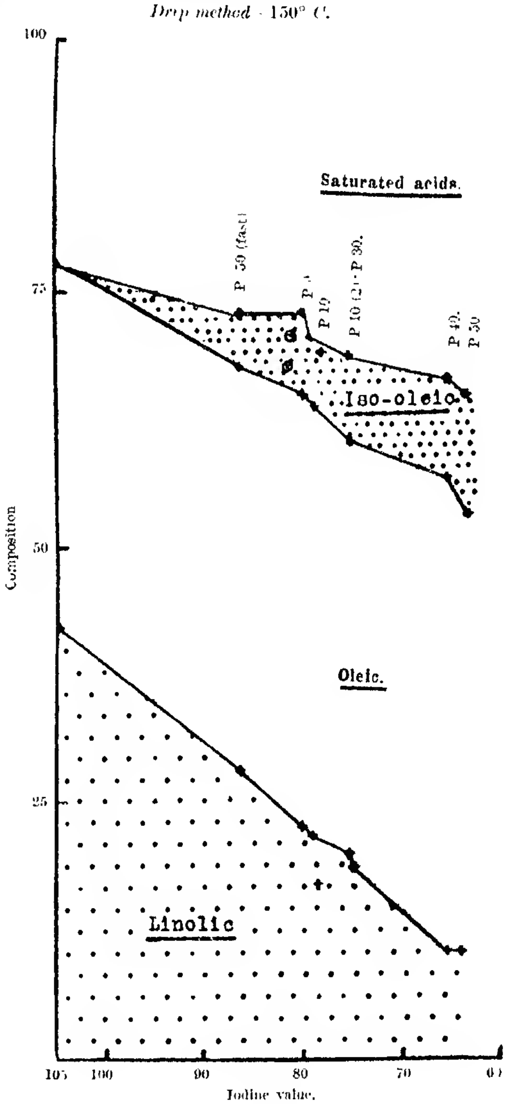

FIG. 2.

and a corresponding increase in saturated acids. At 110° C. the same effect is even more marked—as shown by * in Fig. 2, where the iso-oleic acid

* Read at a meeting of the Birmingham Section on Feb. 5, 1924.
† J., 1923, 219 T.
‡ J., 1919, 320 T.

content is reduced to 3% for an iodine value of 82. These results are consistent with the view that iso-oleic acid is a dehydrogenation product, and it is significant that lower temperatures should result in the relative increase of saturated acids and decrease of iso-oleic acid for the same percentage decrease in linolic acid.

The hydrogenation of pure linolic acid and its glycerides would probably give useful information as to the relation between selective hydrogenation and the formation of iso-oleic acid.

It will be seen from Fig. 2 that change of pressure between the narrow limits of 0 and 50 lb. per square inch has no appreciable influence on the nature or proportions of the products produced, the compositions lying on smooth curves. The same remarks apply to a change in the rate of flow of the oil through the plant between the rates of 12 and 26 lb. per hour.

It therefore seemed probable that it would be possible to measure the effect of pressure on the rate of hydrogenation by determining the hydrogen absorbed in a given time at various pressures.

The small plant in which this investigation was carried out (Fig 3) consisted of a pressure vessel, A, fitted with a graduated glass gauge, *g*, and connected to a hydrogen cylinder provided with a gas-regulating valve, by means of which any given pressure could

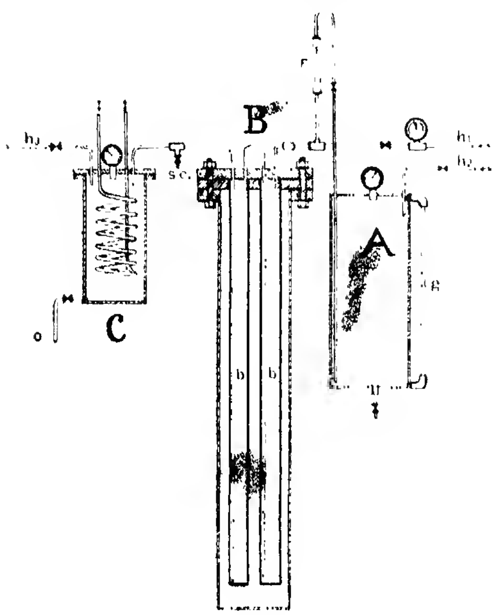

FIG. 3.

be maintained in the vessel. This pressure forced oil through a sight-feed, F, into the hydrogenation vessel, B. The hydrogenation vessel consisted of four tubes, *b*, 1⅜ in. diameter, each 3 ft. long, connected in series and fitting into a steam jacket connected to a small gas-fired steam superheater, C, by means of which any required temperature could be maintained in the tubes. The tubes were connected by a regulating valve to another hydrogen cylinder as shown.

By maintaining a constant pressure-difference between the two vessels, a constant flow of oil passed through the four tubes packed with catalyst; this flow was further regulated by a valve placed behind the sight-feed.

The hydrogen absorbed in any given time was measured by the iodine value of the oil collected in the receiver and run off from time to time by the small cock placed as shown on the return pipe to the pressure vessel. By a manipulation of pressures, the hydrogenated oil could, if necessary, be returned to the pressure vessel without coming in contact with the air.

It had previously been shown that when a constant flow of oil passed through the plant the product obtained had a constant iodine value over very long periods, and it was assumed from this that the factors influencing hydrogen absorption were under control.

When coconut oil, having an iodine value of 8, was passed through the plant at 10 lb. per hour the iodine value was reduced to 0·1, corresponding to 99·8% reduction; this was taken as evidence that all the oil had come into molecular contact with the nickel This may seem surprising. It has, however, been calculated that the average thickness of the oil film is less than 1 mm. and the distance travelled by each particle of oil not less than 3000 mm. under conditions promoting turbulence, thereby reducing oil diffusion effects to a minimum.

On the other hand, when cotton oil was passed through the plant, at the same rate as the coconut oil, the iodine value was not reduced below 25. Since it may be assumed that all the unsaturated oil came in contact with the metal surfaces, it was inferred that the nickel was unable to supply activated hydrogen fast enough to satisfy the requirements of the oil.

It was therefore of interest to study the effect of pressure on a system where hydrogen was rapidly supplied to the catalyst through a thin film of oil capable of removing the activated hydrogen as fast as it was formed.

To measure the effect of pressure, oil was passed through the plant at a constant rate at, say, 10 lb. pressure, for one hour, and the oil collected. The pressure was then raised by 10 lb. and the oil, after running to waste for the next ten minutes, was again collected for an hour at the increased pressure In this way the pressure was raised by 10 lb. at a time to 50 lb. By measuring the oil passed through in a given time and multiplying by the drop in iodine value, a measure of the hydrogen absorbed was obtained.

Table I. shows the result of the first run made to test the effect of pressure. In the last two columns are shown the numbers obtained by dividing the hydrogen absorbed at a given pressure, firstly, by that pressure, and, secondly, by its square root. It will be noticed that the numbers so obtained

decrease in each test where the first power of the pressure is used, but are fairly constant where the square root of the pressure is the denominator.

TABLE I.

Cotton oil hydrogenated at 180° C. at ascending pressures.

Pressure	Rate of flow of oil lb. per ½-hr.	Iodine Value	$\frac{H_2 \text{ abs}}{P}$	$\frac{H_2 \text{ abs}}{\sqrt{P}}$
10	7	66	1035	518
20	6.5	56.3	886	512
30	6.25	50.4	728	490
40	6.25	42.6	686	510
50	6.4	35.1	670	538

Average value of x in P^x 0.52.

By calculation it can be shown that x in $P^x = 0{\cdot}52$ will give the nearest constant. This is obtained from the equation:—

$$x = \log \frac{H_2 \text{ absorbed at } P_1}{H_2 \text{ absorbed at } P_2} \div \log \frac{P_1}{P_2}$$

The assumption involved in this calculation, viz., that the rate of hydrogenation is a linear function of time, will be referred to later.

TABLE II.

Cotton oil hydrogenated at 180° C. at descending pressure.

Pressure	Rate of flow of oil, lb. per ½ hr.	Iodine value	$\frac{H_2 \text{ abs}}{P}$	$\frac{H_2 \text{ abs}}{\sqrt{P}}$
60	6	39.3	500	429
50	6	42.4	559	453
40	6.25	51.6	550	407
30	6	60.0	573	386
20	5.5	65.4	590	350
10	5.5	72.1	677	339
6	6	76.0	1080	117

Average value of x in P^x 0.68.

Table II. shows the results obtained by lowering the pressure by 10 lb. per hour instead of raising it. By this means the effect of any change in catalytic activity can be measured, since in the one case it will tend to decrease the apparent effect of pressure and in the other will tend to increase it. It will be seen that a slightly higher value is actually obtained; this question of change in catalytic activity was, therefore, further investigated.

TABLE III.

Cotton oil hydrogenated at 150° C.

Pressure	Rate of flow of oil, lb. per ½-hr.	Iodine Value	$\frac{H_2 \text{ abs}}{P}$	$\frac{H_2 \text{ abs}}{\sqrt{P}}$
6	7	80.0	768	351
10	5.75	78.7	558	279
20	6.35	77.	176	281
30	6.5	74.8	407	277
40	6.25	65.5	425	317
50	6.8	65.8	397	322
50	13.4	81.3	379	308
10(2)	5.5	75.3	609	305

Average value of x in P^x 0.68.

For the experiment recorded in Table III. ascending pressures were used, as in the test detailed in Table I., and, after reaching a pressure of 50 lb., the rate of flow of oil was doubled both to measure its effect and also to have approximately the same iodine value as would be obtained later when the pressure was lowered.

It will be seen that:—

(a) the average value for x is in agreement with that obtained in the last experiment;

(b) doubling the rate of flow of oil has not altered the amount of hydrogen absorbed;

(c) there has been no loss in catalytic activity within the rather wide limits of experimental error.

It will be noted that the temperature of this experiment was 150° C. as against 180° to 190° C. for the two others.

TABLE IV.

Palm kernel oil hydrogenated at 180° C. with fresh catalyst.

Pressure	Rate of flow of oil lb. per hour	Iodine value	$\frac{H_2 \text{ abs}}{P}$	$\frac{H_2 \text{ abs}}{\sqrt{P}}$
50	6	0.7	131	106
40	6	0.2	160	118
30	6.3	1.4	198	135
20	6	3.5	196	114
10	6	4.2	254	128
50	6	1.8	121	98
50	12.4	7.5	138	115

Average value of x in P^x 0.11.

Table IV. shows the effect of pressure on the hydrogenation of palm-kernel oil down to low iodine values; as would be expected, a low value is obtained for x.

TABLE V.

Coconut oil hydrogenated at 180° C.

Pressure	Rate of flow of oil lb. per hour	Iodine value	$\frac{H_2 \text{ abs}}{P}$	$\frac{H_2 \text{ abs}}{\sqrt{P}}$
50	6	0.7	131	106
40	6	0.2	160	118
30	6.4	1.4	198	120
20	6	3.5	196	111
10	6	4.2	241	128
50	6	1.8	121	98.4
50	12.4	7.5	138	115

Average value of x in P^x 0.2.

Table V. The value for x obtained by the use of coconut oil, which has an initial iodine value of only 8, shows how the effect of pressure is overshadowed by "mass-action" effects, and indicates moreover that every particle of the oil comes in contact with nickel at some stage in its progress through the plant.

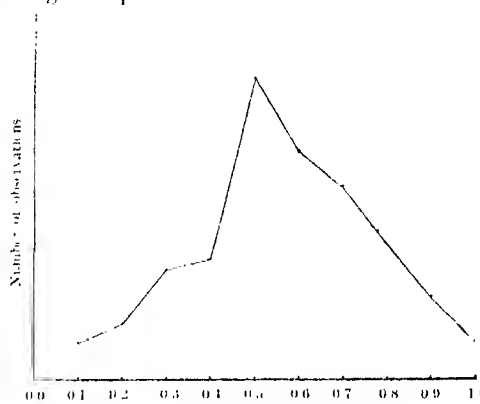

FIG. 4.

Fig. 4 shows a graphic representation of the results of numerous experiments to determine the value of x in P^x.

As one of the main objects of this investigation was to measure the influence of rate of flow of oil and pressure on the iodine value of the resulting product, experiments were undertaken in which

these two factors were varied simultaneously so as to maintain a constant iodine value.

TABLE VI.

Rate of flow calculated to x in P^x = 1 on cotton oil. Temp. 180° C.

Pressure	Rate of flow of oil lb. per hour	Iodine value	$\frac{H_2\ abs.}{P}$	$\frac{H_2\ abs.}{\sqrt{P}}$

10	5	46.6	1115	558
20	7	56.1	926	550

Average value of x in P^x 0.60

Table VI. shows the effect of making the rate of flow of oil proportional to the pressure. It will be seen that the iodine value of the resulting product rises with increase of pressure, as was to be anticipated from previous experiments.

TABLE VII.

Rate of flow calculated to x in P^x 0.5 on cotton oil. Temp. 180° C.

Pressure	Rate of flow of oil lb. per hour	Iodine value	$\frac{H_2\ abs.}{P}$	$\frac{H_2\ abs.}{\sqrt{P}}$
10	5	56.8	1010	480
20	5.8	50.6	911	537
30	6.6	55.0	735	480
40	7.4	57.7	615	452
50	8.4	52.3	668	503
10	5	51.2	1135	500

Average value of x in P^x 0.48.

Table VII. shows the effect of making the rate of flow of the oil proportional to the square root of the pressure. The results, while varying among themselves, show no tendency to vary with the pressure.

TABLE VIII.

Rate of flow calculated to x in P^x = 0.5 on ground-nut oil. Temp. 180° C.

Pressure	Rate of flow of oil lb. per hour.	Iodine value	$\frac{H_2\ abs.}{P}$	$\frac{H_2\ abs.}{\sqrt{P}}$
10	9	56.1	1225	614
20	10.6	57.2	1000	502
30	12	60.1	804	540
40	13.3	58.8	780	564
50	14.4	64.8	561	458
10	9	61.7	1026	514

Average value of x in P^x 0.4.

Table VIII. shows a repetition of the previous experiment with ground-nut oil; here again the effect of pressure is not marked.

It would, therefore, appear that in this method of hydrogenation for industrial purposes it can be assumed that the output of hydrogenated oil of a given iodine value will be proportional to the square root of the pressure.

A similar series of experiments has been undertaken to measure the effect of varying the rate of flow of oil between 5 lb. and 30 lb. per hour on the rate of hydrogen absorption. In general it has been found that between these limits the amount of hydrogen absorbed is independent of the rate of flow of oil and, therefore, of the iodine value of the oil, provided the iodine value does not fall below about 30 or the rate below 5 lb. per hour. This would indicate that the rate of hydrogen absorption is a linear function of time between those limits. This is in agreement with the experiments of other workers, though not necessarily for the same reason, and details of the experiment are, therefore, not of particular interest.

It is not surprising that dissimilar results should have been obtained by the use of a method in which the relationship between the nickel, hydrogen, and oil is varied in a different manner from that usually obtaining with powder catalysts.

The process of hydrogenation of oil may be divided into three stages.

The first stage consists in the solution of hydrogen in the oil and its diffusion to the surface of the catalyst; it is probable that this is in general the limiting factor in reaction velocity where powder catalysts in small percentages are employed.* In such a case the reaction velocity would be linear and proportional to the pressure.

The second stage consists in the condensation of the hydrogen on to the nickel and its appearance at the surface, or, possibly, evaporation from the surface, in an activated form. If the latter condition is the limiting factor and the activation consists in the production of atomic hydrogen, then the reaction velocity will be proportional to the square root of the hydrogen pressure and will probably be linear.

The third stage consists in the combination of the activated hydrogen with the ethylene linkages of the unsaturated oil, and if it were possible to measure this factor alone the reaction velocity would probably be independent of the pressure and represented by a curve of a modified logarithmic type.

It is the object of this communication to show that there is some evidence for the second stage of hydrogenation having been realised in practice.

The author desires to express his thanks to Messrs. G. H. Hawker and H. H. Foster for their co-operation in the laboratory and model-plant trials respectively, and to Technical Research Works, Ltd., in whose laboratories the investigation was undertaken.

THE VAPOUR PRESSURES OF FUMING SULPHURIC ACID, AND THEIR APPLICATION TO THE PROBLEM OF THE ABSORPTION OF SULPHUR TRIOXIDE.

BY J. W. MCDAVID, D.SC., F.I.C., M.I.CHEM.E.

In the manufacture of fuming sulphuric acid by the contact process, the sulphur trioxide produced in the converter, after being cooled to some extent, is usually absorbed in a series of bubbling vessels containing sulphuric acid, or in towers in which sulphuric acid is circulated. In these absorbers the acid and gas generally travel countercurrent, that is, the gas richest in sulphur trioxide meets the strongest acid in the first vessel and then passes to the second absorber where it is brought into contact with a slightly weaker acid. This process is repeated throughout the whole series of absorption vessels, until finally the gas leaving the last absorber is practically free from sulphur trioxide.

It is well known that in order to remove the last traces of sulphur trioxide the acid in the last absorber should contain about 98·5% H_2SO_4. If stronger acid than this be used sulphur trioxide is not absorbed owing to the fact that the acid has a vapour pressure of sulphur trioxide. If, on the other hand, the acid in the last absorption vessel contains less than about 98·5% H_2SO_4, sulphuric acid mist is formed which is very difficult to absorb. In practice satisfactory results are obtained if the acid in the last vessel is kept about 97%–99% H_2SO_4. As a rule it is necessary to operate the absorption plant in such a way that the strength of the oleum delivered from it remains more or less constant, and while in the past it has been possible to achieve both these objects, they have very often been attained rather by good fortune than by a scientific study of the problem.

It occurred to the author that it was possible, by assuming a theoretically perfect absorption system, to determine exactly the conditions governing the production of oleum of any given strength, and that the results so obtained would be applicable, with a sufficient degree of accuracy, to most of the absorption systems employed in modern oleum plants.

The object of the present paper is to describe the method of calculation employed, to show how the conditions may be varied to meet any particular case, and to indicate how closely actual practice approximates to theory.

The method does not give any information regarding the size of absorption vessels required for any given output, but it may form a convenient starting point for experiments on this problem.

In attacking this problem of absorption it was obvious at the outset that a knowledge of the vapour pressures of oleum at different concentrations and temperatures was necessary, and as the results obtained by extrapolation from the figures given by Knietsch* were unsatisfactory, vapour pressure measurements were made over the range of temperatures and concentrations required. For this purpose a dynamic method was employed in which the conditions were similar to those which usually obtain in plant absorption systems.

A mixture of purified burner gas and air was dried by means of concentrated sulphuric acid and passed over a catalyst, so that practically 98% of the sulphur dioxide was converted into trioxide. The gas was then passed directly into a small bubbler containing sulphuric acid or oleum. The bubbler was placed in a thermostat, the temperature of which was kept constant to within about 1° C. The concentration of sulphur dioxide in the mixture was maintained as constant as possible by the aid of gas flow meters, the composition of the mixture being checked frequently by means of the Reich test. From the percentage of sulphur dioxide in the gas entering the catalyst tube and the percentage conversion, the concentration of sulphur trioxide in the gas entering the bubbler was determined. Samples of the acid used to absorb the sulphur trioxide were drawn from time to time and analysed until the composition was found to be constant, showing that equilibrium had been attained. The results of these determinations are given in Table I., while they are shown graphically in a more convenient form by means of the smoothed curves in the accompanying figure.

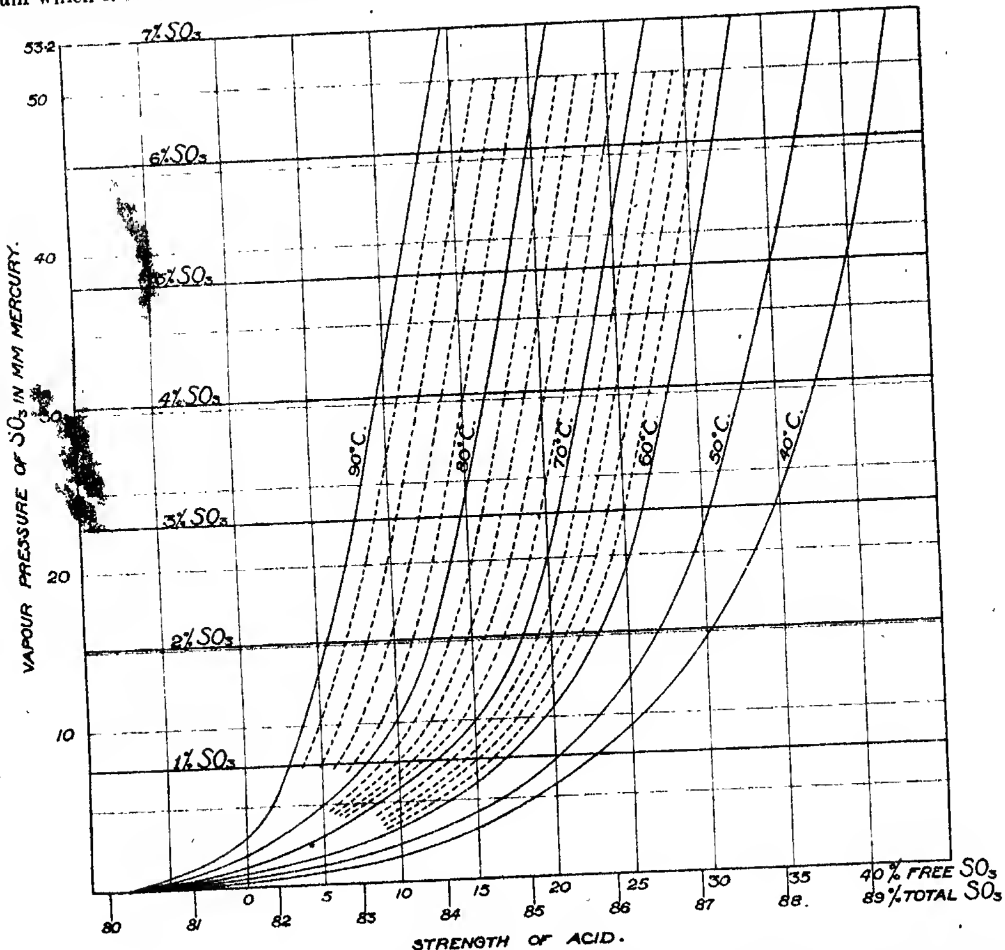
* Ber., 1901, 34, 4111.

It will be observed that on the figure, in addition to the vapour pressure curves, a number of horizontal lines have been drawn, denoting the percentage concentration by volume of sulphur trioxide corresponding to the pressures in mm. of mercury. By the aid of these horizontal lines it is possible to determine immediately the maximum strength of oleum which it is theoretically possible to produce from any gas at any temperature within the range given.



For example, to determine the maximum strength of oleum which can be produced from a gas containing 3% SO_3 at a temperature of 50° C., find the strength of oleum corresponding to the point where the 3% SO_3 line cuts the 50° C. isothermal. This point corresponds to 30·5% free SO_3, which is therefore the maximum strength of acid which can be produced under those conditions.

In order to apply these vapour pressure data to the solution of general problems of sulphur trioxide absorption, it is necessary to make two assumptions, based on the original assumption of a theoretically perfect absorption system. In the first place it is assumed that the concentration of the acid is constant throughout the whole absorber, whether the latter be of the bubbler or tower type, and further that this concentration is the same as that of the acid leaving the absorber. In a well designed apparatus this is practically true, especially in the bubbler type, while in towers it is almost equally true provided that the rate of circulation of acid is great compared with the rate at which the acid is forwarded from one tower to the next.

Secondly, it is assumed that the gas leaving each absorption vessel is in equilibrium with the acid contained in that vessel, that is, that the partial pressure of the sulphur trioxide in the gas leaving the absorber is equal to the vapour pressure of the oleum in the absorber. Here again, if the absorption apparatus is well designed and is not overloaded this assumption will be approximately correct.

The course of absorption is then found to depend on: (1) The total weight of sulphur trioxide entering the system in a given time; (2) the concentration of sulphur trioxide in the gas entering the system; (3) the strength of the oleum being produced; (4) the strength of absorption acid fed into the last absorber of the system; (5) the temperature of the acid in each absorption vessel. If these conditions are fixed, the number of absorption vessels required for complete absorption can readily be calculated.

The amount of sulphur trioxide absorbed in the first vessel will be equivalent to the difference between the partial pressure of the sulphur trioxide in the gas entering the absorber and the vapour pressure of the oleum contained in that absorber, which in turn depends on the temperature of the acid. The quantity of sulphur trioxide unabsorbed in this vessel will, of course, be equivalent to the vapour pressure of the oleum in the vessel.

The weight of oleum leaving the first absorber, which is the whole of the production, can readily be obtained by calculation from the weight of sulphur trioxide entering this absorber and from the strength of absorption acid fed to the last vessel. For example, if the oleum being produced contains 20% of free SO_3 and the acid fed to the absorption system contains 95% of H_2SO_4, a simple arithmetical calculation shows that for every ton of SO_3 entering the system 2·89 tons of 20% oleum are produced. At the same time the weight of absorption acid required is found to be 1·89 tons of 95% H_2SO_4. From the weight of sulphur trioxide and oleum leaving the first vessel and the weight of sulphur trioxide entering this vessel, it is possible by equating input to output to determine the weight and strength of the acid entering the first absorption vessel from the second vessel. The course of absorption in the first vessel is therefore determined.

According to one of the assumptions made, the acid contained in the second vessel is of the same strength as that which is passed on from the second vessel to the first, and the strength of this has been determined above. If now the temperature in the second vessel is fixed, the vapour pressure of this acid can be determined from the graphs and hence the quantity of sulphur trioxide passing unabsorbed through the second vessel can be found. The quantity of sulphur trioxide entering the second vessel is that which passes unabsorbed through the first, and the weight of acid leaving the second is that which enters the first. Therefore, by equating input and output in the second vessel the weight and strength of acid leaving the third vessel and entering the second can be determined. The above process is repeated for the third vessel and is continued until the whole of the sulphur trioxide is absorbed. This will not occur until an absorber is reached which contains acid of not more than 98·5% H_2SO_4. It may happen that the calculation shows that the acid in the last vessel must be of considerably lower strength than 98·5% H_2SO_4, in which case absorption might be unsatisfactory owing to the formation of mist. In such a case the conditions must be altered in such a way as to produce the required result. This point will, however, be dealt with more fully at a later stage.

The method of calculation outlined above will be more clearly followed by the aid of the following examples.

Example 1.—To determine the number of absorption vessels required to deliver 20% oleum from a plant producing 10 tons of sulphur trioxide per day, the concentration of SO_3 in the gas being 7%, the strength of the absorption acid 97% H_2SO_4, and the temperature in each of the absorption vessels 76° C.

Calculation shows that the weight of 20% oleum produced from 10 tons of sulphur trioxide and 97% sulphuric acid is 33·96 tons containing 28·97 tons of total SO_3.

From the curves the vapour pressure of 20% oleum at 76° C. is found to be 34·6 mm., and this is the partial pressure of SO_3 in a gas containing $34{\cdot}6 \times 100 \div 760 = 4{\cdot}55\%$ SO_3.

Hence the gas leaving the acid in the first absorber will contain 4·55% SO_3. Assuming that the change in the total volume of the gas is negligible (it can, of course, be allowed for if necessary), the weight of sulphur trioxide in the gas leaving the first absorber is, since a 7% SO_3 gas represents 10 tons, $4{\cdot}55 \times 10 \div 7 = 6{\cdot}50$ tons of SO_3.

Equating the total materials leaving the first absorber to the total materials entering we have:—

	Total Tons.	SO_3 Tons.	H_2O Tons.
Weight of acid leaving 1st vessel .. .	33·96	28 97	4 99
,, ,, SO_3 as gas ,, ,, ...	6 50	6 50	—
Total materials leaving 1st vessel .. .	40 46	35 47	4·99

This is equal to the materials entering the first vessel, and since the weight of SO_3 entering in the form of gas is 10 tons, the weight and composition of the acid entering from the second vessel can be obtained by difference, thus:—

	Total Tons.	SO_3 Tons.	H_2O Tons.
Total materials entering 1st vessel ..	40·46	35·47	4·99
Weight of SO_3 as gas ,, ,, ,,	10·00	10·00	—
Hence weight of acid ,, ,, ,,	30·46	25 47	4·99

The acid entering the first vessel thus contains $25{\cdot}47 \div 30{\cdot}46 \times 100 = 83{\cdot}6\%$ $SO_3 = 10{\cdot}8\%$ oleum, and this is therefore the strength of the acid in the second absorber.

The vapour pressure of 10·8% oleum at 76° C. = 8·4 mm., which is equivalent to $8{\cdot}4 \times 100 \div 760 = 1{\cdot}11\%$ SO_3, and this represents $1{\cdot}11 \times 10 \div 7{\cdot}0 = 1{\cdot}58$ tons of SO_3, which is the amount which escapes the second vessel and passes on to the third; again, equating input and output in the second vessel we have:—

	Total Tons.	SO_3 Tons.	H_2O Tons.
Weight of acid leaving 2nd vessel	30 46	25·47	4·99
,, ,, SO_3 gas ,, ,, ,, ...	1·58	1·58	—
Total materials leaving 2nd vessel ..	32 04	27·05	4·99
Weight of SO_3 gas entering ,, .. .	6 50	6·50	—
∴ Weight of acid ,, ,, ,, ...	25·54	20·55	4·99

∴ Strength of acid entering the 2nd vessel = 80 47% SO_3 = 98·58% H_2SO_4.

Hence the strength of acid in the third absorber is 98·5% H_2SO_4, and since this has no vapour pressure,

theoretically the whole of the remainder of the SO_3 will be absorbed in this vessel. In other words, three absorption vessels in series are required to complete the absorption.

Since the vapour pressure of oleum depends to such a large extent on the temperature, it is obvious that the efficiency of absorption in the first vessel and consequently the number of absorption vessels required in any particular case, depend upon the temperature at which this absorption takes place. For example, if the temperature of absorption is 60° C. instead of 76° C., as in the problem solved above, it would be found that two vessels in series were sufficient to give complete absorption, as the strength of the acid in the second vessel would be 98·9% H_2SO_4, which exerts practically no vapour pressure of SO_3. On the other hand, if the temperature of absorption were 80° C., four vessels in series would be necessary.

It can also be shown in this way that the weaker the absorption acid employed the higher is the temperature at which absorption can be allowed to take place for a given number of absorption vessels. For example, using a water feed, absorption at 77° C. would be complete in two vessels, whereas, as has been shown, three vessels are required using 97% C.O.V. at 76° C.

As has already been mentioned, it is essential that the strength of acid in the last vessel should be 98%–99%. If calculation gives a stronger acid than this then obviously either another absorption vessel is required or a lower temperature must be employed in the earlier stages of absorption. Another method is to use a lower strength of absorption acid and repeat the calculation. If, on the other hand, calculation shows that the acid in the final stage contains less than 98% of H_2SO_4, then either the temperature in the earlier stages should be raised, or it should be lowered sufficiently to bring the acid in the last stage but one down to 98% H_2SO_4, when the last absorber can be cut out. Variation in the strength of the absorption acid here will also have a similar effect.

Example 2.—It is required to produce 25% oleum in a series of three absorption vessels from a gas containing 7% SO_3 and a feed acid containing 95% H_2SO_4. Determine convenient temperatures at which the first and second absorbers must be maintained.

There are an infinite number of combinations of temperatures which will satisfy the conditions of this problem, and any two of these may be selected. This will be more clearly seen when the example is worked out.

Since the number of absorbers is fixed at three, it is convenient in this case to commence the calculation with the input to and output from the last absorber; 95% H_2SO_4 is fed into this absorber, and in order to obtain the best absorption the acid in this vessel should be maintained at about 98·5% H_2SO_4.

[illegible]orking out this example the actual weight of [illegible]duced per day is not required, but any con[illegible] figure, such as 10 tons per day, may be [illegible]sumed. Calculation shows that 10 tons of SO_3 require 15·89 tons of 95% H_2SO_4 to produce 25·89 tons of 25% oleum. A further calculation shows that 15·89 tons of 95% H_2SO_4 must absorb 2·32 tons of SO_3 in the third absorber to produce 98·5% H_2SO_4, and this must be the total amount of SO_3 entering the third vessel, since absorption is complete here.

Equating input and output for the last vessel we have :—

	Total Tons.	SO_3 Tons.	H_2O Tons.
Acid entering 3rd vessel	15·89	12·33	3·56
SO_3 „ „ „	2·32	2·32	—
∴ Acid leaving 3rd vessel =	18·21	14·65	3·56

Now if 10 tons of SO_3 are equivalent to 7% by volume, 2·32 tons=1·62% by volume=12·3 mm. Hg partial pressure.

The acid in the second vessel must therefore have a vapour pressure equivalent to 12·3 mm. of mercury and the strength of this acid will therefore depend on the temperature. This is obvious by referring to the vapour pressure curves.

We can therefore at this point assume any convenient value for the temperature of the acid in the second vessel. For example, assume that the second vessel is at a temperature of 65° C., then the acid contained in it must consist of 19% oleum (=85·1% total SO_3), for this is the acid which at 65° C. exerts a vapour pressure of SO_3 equal to 12·3 mm.

In the second vessel 18·21 tons of 98·5% sulphuric acid are converted, by the absorption of sulphur trioxide, into 19% oleum, and to accomplish this, 5·59 tons of SO_3 are required. A total of 23·80 tons of 19% oleum thus flows from the second vessel to the first.

Equating input and output in the second vessel we have :—

	Total Tons.	SO_3 Tons.	H_2O Tons.
Acid leaving 2nd vessel	23·80	20·24	3·56
SO_3 „ „ „	2·32	2·32	—
	26·12	22·56	3·56
Acid entering 2nd vessel	18·21	14·65	3·56
∴ SO_3 entering 2nd vessel =	7·91	7·91	—

7·91 tons of SO_3 are equivalent to 5·54% by volume or to a partial pressure of 42·1 mm. 42·1 mm. must therefore be the vapour pressure of the acid (25% oleum) in the first vessel, and by referring to the curves it is found that the temperature at which 25% oleum has a vapour pressure of 42 mm. is 70·5° C. Hence, if the first vessel is kept at 70·5° C., and the second at 65° C., the results desired will be obtained.

Any number of other solutions of this problem can be obtained in a similar manner by assuming other temperatures for the second vessel. Since the amount to be removed by the third vessel is fixed, it follows that if the temperature in the first vessel is raised the temperature in the second vessel must be lowered, and *vice versa*.

There are some practical advantages to be obtained in carrying out absorption in only two stages.

Suppose, for example, that in the above problem the absorption is to be carried out in only two absorbers. In this case there is only one temperature which will satisfy the conditions laid down. The

second vessel must now contain 98·5% H_2SO_4, and therefore the acid and gas balance for this stage is the same as for the third stage in the previous calculation. There are thus 2·32 tons of SO_3 passing from the first absorber to the second, and this amount is equivalent to a vapour pressure of 12·3 mm. The temperature of the 25% oleum in the first vessel must therefore be such that its vapour pressure is 12·3 mm.; a temperature of approximately 50° C. satisfies this condition.

Attention must be drawn to the fact that while the temperature of the acid is approximately uniform in each vessel of an absorption system of the bubbler type, this is not quite true when dealing with towers. In the latter case it is the temperature of the acid in the region of the gas outlet that controls the amount of sulphur trioxide which passes to the next effect. The temperature at the acid outlet cannot, however, be disregarded altogether, since it is this temperature which controls the maximum strength of acid which it is possible to produce.

Practical results obtained.

It is of interest to compare the practical results obtained on a large-scale absorption plant consisting of three bubbling vessels working under ordinary routine conditions, with the calculated results obtained by the method given above.

The results given on the left hand side of Table II. were determined by actual experiment, while those on the right-hand side were calculated using the figures given in brackets as data. Thus in the first example given in the table the course of absorption in three vessels has been calculated for the case of a system producing oleum containing 85·27% of SO_3 from a gas with an SO_3 content of 6·7% and a feed acid containing 77·66% of SO_3, the temperature in the first absorber being 71° C. and in the second 63·5° C.

TABLE II.

Comparing practical results obtained on an absorption system with the calculated results.

Expt. no.		Practical results. Absorber no. 1.	Absorber no. 2.	Absorber no. 3.	Exit.	Calculated results. Absorber no. 1.	Absorber no. 2	Absorber no. 3.	Exit.
1	% SO_3 in gas entering ..	6·7	2·18	0·15	0·07	(6·7)	2·76	0·11	nil.
	Strength of acid (total SO_3)	85·27%	81·2%	77·6%	—	(85·27)	81·68	77·90	
	Temp. of acid	71° C.	63·5°	27·5°		(71° C.)	(63·5°)		
	% SO_3 in acid fed			77·66				(77·66)	
2	% SO_3 in gas entering ..	7·14	1·34	nil.	nil.	(7·14)	1·92	nil.	nil.
	Strength of acid (total SO_3)	85·03	81·1	77·9		(85·03)	80·41	77·0	
	Temperature of acid	69° C.				(69° C.)			
	% SO_3 in acid fed			77·96				(77·96)	

The calculated results in Table II. agree very well with those actually determined, and it is interesting to observe that in both cases absorption is shown to be complete in the second vessel, and that the third vessel under these conditions is superfluous.

Whilst the method described above does not give any information regarding the size of absorption vessel required for any given output, it is of some assistance in the design of plant, since it defines the amount of absorption which takes place in each vessel. This being known, the heat liberated in each vessel can be determined from the temperature of the gas entering the first vessel and by the aid of Porter's data,* and so the amount of cooling liquid required in each absorber can be estimated.

The practical work in connexion with the vapour pressure determinations was carried out by Mr. W Green, to whom the author conveys his thanks He also desires to thank the management of Messrs Nobel Industries, and especially Mr. W. Rintoul O.B.E., F.I.C., for granting permission to publish the results of this work.

THE EVAPORATION RATE OF SOME SOLUTIONS.

BY L. S. BAGSTER.

A considerable mass of information is available as to the rate of heat transfer in vacuum evaporation, but most of the data refer to water. The present work was undertaken in the hope of obtaining information relative to the new factors introduced by dissolved substances.

The apparatus used was of copper (see Fig. 1), and consisted of a unit constructed to reproduce as nearly as possible the effect of a single tube of a calandria evaporator. The evaporating tube, A, 61 cm. (2 ft.) long and 5·1 cm. (2 in.) in diameter, was surrounded by an outer tube 7·6 cm. (3 in.) in diameter. The ends of the annular space, which served as steam jacket, were closed by flat plates 3 mm. thick. Steam was admitted to the jacket by the pipe, B, and distributed by the small branch pipes along the length of the jacket. Condensed steam was discharged through the valve, C. The valve, D, served as a vent to prevent accumulation of air in the steam space. The outside of the steam space and the admission and escape pipes were surrounded by a jacket packed with a mixture of asbestos and magnesia, furnishing a layer of insulation about 1 in. thick, thus ensuring that the only appreciable heat transfer was through the wall of the evaporation tube and the top and bottom tube plates. The evaporator unit was enclosed in a cylindrical vessel, 26 cm. diameter and 150 cm. high, the outside being covered with magnesia boiler lagging. This vessel contained the solution to be evaporated. The top of the vessel contained a splash retainer and was connected to a multitubular condenser. Condensate was collected in a large

* Trans. Faraday Soc., 13, 373–400.

calibrated bottle, attached to which was a removable receiver into which could be drawn the condensate after measurement, without disturbing the continuity of evaporation.

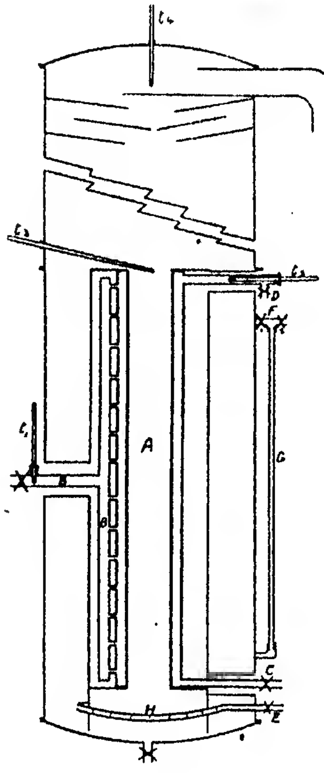


Fig. 1.

A gauge-glass, G, was attached to the body of the evaporator for controlling the liquor level. This gauge was fitted at the top with valves, F_1, F_2, which allowed the admission of air to clear the glass of liquor, thus permitting its being filled with fresh solution if necessary. Steam pressure and temperature were controlled by two hand valves in series, the temperature being read by the thermometers (t_1 on the inlet pipe and t_2 on the vent pipe). The pressure was controlled by a valve in the pipe leading to the air pump, which was opened until the pump could reduce the pressure beyond the desired value. Air was then admitted by a needle valve to the suction pipe connecting the apparatus to the first valve and air pump, until the desired vacuum was reached. Both steam pressure and vacuum could be closely maintained for long periods with little attention. To maintain constant steam conditions and to prevent accumulation of water in the steam space, steam was kept blowing from the vent valve, D, and along with the condensed steam, from the drip valve, C. In working with solutions it was necessary to maintain a constant composition of liquor, replacing the water as fast as it evaporated; this was done by admitting condensed steam from C at a temperature just below that of the liquor, by means of the needle valve, E, and the perforated pipe, H, maintaining constant level on the gauge, G. During evaporation the vapour carried through the tube, A, a violent spray of liquor, which fell through the annular space between the heating section and the wall of the containing vessel, mixing with the added water from H. This method of working eliminates any effect due to heat of solution. The temperature of the boiling liquor was read on the thermometer, t_2, having its bulb set over the top of the evaporator tube and kept wet by the spray. The corresponding temperature of the vapour was obtained from the thermometer, t_4, in the opening of the vapour outlet pipe.

It has been shown by Webre (J. Ind. Eng. Chem., 1918, **10**, 191) for the calandria type of evaporator that over a certain range of immersion of the evaporator tubes in the liquor, the heat transfer varies but slightly, and takes place from the tube wall to the liquor sprayed over it by the rapid stream of vapour. In the present case preliminary tests with water and sugar solution showed a nearly constant evaporation rate for immersions varying from about 25 cm. to 40 cm. The measurements were all carried out with a depth of 33 cm.

The various factors that influence heat transfer in vacuum evaporation have often been discussed (see Badger and Shepard, Chem. and Met. Eng., 1920, **23**, 237). It is well known that the rate of evaporation depends largely on the rate of movement of evaporating liquor over the heating surface, and hence it would be expected that the viscosity of a solution would influence the rate of evaporation. For the present work solutions of several very soluble substances having different viscosities were selected, the rate of evaporation being determined over as wide a range of concentration as possible in each case. To secure comparative results the steam temperature was always maintained at about 105° C., being held constant during an experiment. The liquor was maintained always with a surface boiling temperature of 80°, the temperature being maintained for solutions of different concentration by variation of the pressure. There was thus secured a nearly constant temperature difference between steam and liquor, and variations in the quantity of water evaporated are then due to other factors.

The results of a series of determinations of the amount of evaporation are given in the accompanying table, where each figure is the mean of several determinations agreeing to about 1%. The compositions are expressed as percentages by weight of dissolved substance. The temperatures have been corrected for thermometer errors.

The results are given in grams of water evaporated per hour per degree temperature difference, and were determined on runs of 10 or 15 minutes, according to the rate of evaporation. The actual quantities evaporated can be calculated from the temperature figures in the table. Included in the figures is a small correction for heat loss from the evaporato

body. This was determined by passing dry steam through the body and measuring the volume of condensed water deposited, which, under the working conditions, was about 100 grams in 10 minutes.

The true temperature difference between steam and liquor is obviously not represented by the difference between steam temperature and the surface temperature of the liquor, as at the bottom of the evaporator tube the boiling temperature of the liquor will be increased owing to the extra pressure of the liquid. The average temperature of the liquid must be considered, and to determine this the bottom temperature was calculated as follows. The thermometer in the head of the evaporator gave the boiling temperature of water at the pressure in the evaporator. The excess pressure due to the head of liquid could be calculated from its weight and density, and from "Landolt-Börnstein Tabellen" the boiling temperature of water under the excess pressure at the bottom was obtained. As the boiling temperature increase is small, the difference between boiling temperature of water and of solution will be nearly the same at the top and bottom of the tube, hence by adding to the calculated boiling temperature of water at the bottom the difference between the boiling temperature of water and solution at the liquor surface, the boiling temperature of the liquor at the bottom was obtained. The mean liquor temperature is the mean of the top and bottom temperatures and is the value used in calculating the evaporation rate per degree.

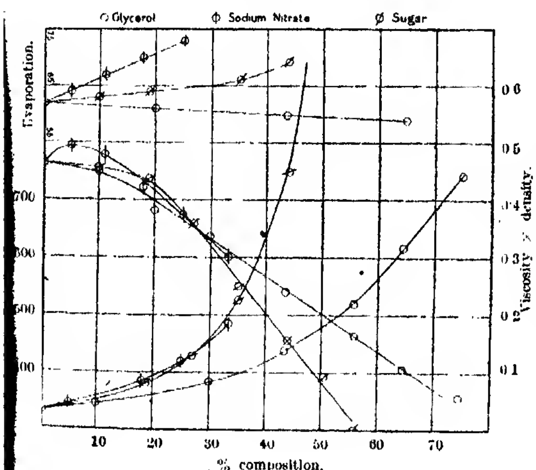

Fig. 2.

The value given for water is not the maximum quantity possible, but was determined after the tube had been tested and allowed to stand for some months. A surface film developed which somewhat reduced the rate of evaporation, but the value remained practically constant during the course of the experiments. This water value was determined before and after every series of measurements and several times during a day's run.

Included in the table are values for viscosity and surface tension, both of which appear to affect the evaporation rate. The viscosity determinations were made at 80° by means of an Ostwald capillary viscosimeter standardised by water. The densities at 80° necessary for viscosity calculations were obtained (by extrapolation if necessary) from data in "Landolt-Börnstein," the decrease in density from 20° being about 3% in most cases. The surface tensions were measured at 80° by a modified capillary tube method, measuring by water gauge the air pressure necessary to depress the meniscus to a mark on the capillary.

The substances tested were first-grade commercial cane sugar, pure glycerol, commercial sodium nitrate, and commercial sodium sulphate. The solutions were prepared by weight and samples drawn during measurement were tested by density, and in the case of sugar, by rotation measurement. The percentage compositions by weight for sugar solutions of varying density were taken from Geerligs' "Cane Sugar," for glycerol from the figures of Gerlach and Skalweit collected in Lamborn's "Soap, Candles, and Glycerine," and for the sodium salts were obtained from Comey's "Dictionary of Solubilities."

From the percentage compositions and densities of the various solutions the volume percentages of water and the molecular concentrations have been calculated and three sets of curves drawn, showing the relation between evaporation and composition expressed in the three forms. Viscosity and surface tension values are included in each set. As the resistance to flow of the solutions up the evaporator tube may be regarded as proportional to viscosity and density, the quantity "viscosity × density" is shown on the curves and will be referred to as "viscosity" in the discussion.

It might be expected that increase in viscosity would lead to decrease in rate of evaporation, and increase in concentration might be expected to

produce a similar result, partly at least on account of displacement of water by dissolved substance leading to lesser rate of contact between water and heating surface. It will be shown presently that the effect of concentration is most nearly represented by the volume percentage of water, so that in the curves of Fig. 3 where concentration is represented by water volume the deviation of the curves from one another requires further discussion. Viscosity of itself is insufficient to account for the variation in the case of the dilute solutions, where sodium nitrate, with a

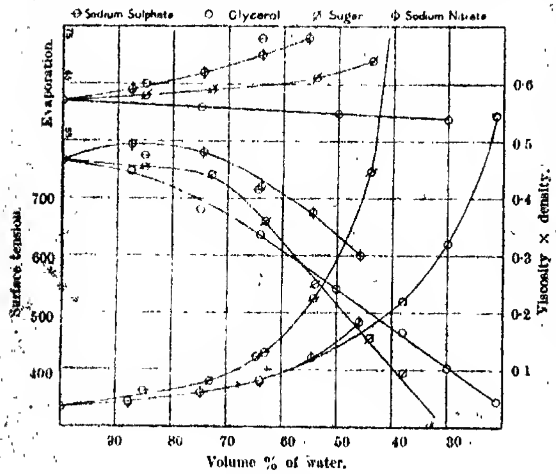

Fig. 3.

viscosity greater than water, shows actually a greater rate of evaporation (a similar result is seen from the table for sodium sulphate, which was not included on the curve to avoid confusion), while the more viscous sugar solutions show a greater rate of evaporation than the less viscous glycerol solutions. These results are consistent with the idea that surface tension is a controlling factor when viscosity and concentration are small, higher surface tension leading to greater evaporation. Greater tension may be expected to cause quicker breaking of bubbles and films with quicker re-establishment of contact between solution and heating surface and consequent greater rate of heat transfer. The actual rates found are, of course, due to surface tension modified by viscosity. Sodium sulphate, with a greater tension than the nitrate, has the lesser evaporation rate corresponding with a greater viscosity, while the sugar solutions, though the tensions are slightly greater than water, have smaller rates, again corresponding with greater viscosity. In the case of glycerol solutions the lower viscosity is insufficient to counteract the effect of lower surface tens[illegible] the curve falls below that of the sugar solution[illegible]

In the case of t[illegible] concentrated solutions where, judging by th[illegible] dilute solutions, surface tension may be co[illegible] of less relative importance, volume percentage [illegible]ter and viscosity seem to be the controlling factors, percentage or molecular concentration having less influence. It will be seen in Fig. 3 that sodium nitrate and sugar solutions of the same viscosity have, for a considerable range, nearly the same volume percentages of water and evaporation rates, though the nitrate solutions have much the greater molar concentration. On the other hand, in the case of glycerol and nitrate solutions of the same viscosity it will be seen from Fig. 4 that, allowing for the dissociation of the nitrate, its actual molar concentrations are greater than for corresponding glycerol solutions, yet the evaporation rates for the nitrate are much greater, corresponding to greater volume percentages of water. In the case of glycerol and sugar solutions of the same volume percentage of water, the evaporation is less for the more viscous sugar solutions, though the sugar solutions have the smaller molar concentration.

Except in the case of very concentrated sugar solutions, where increase in concentration leads to great increase in viscosity, reduction in volume percentage of water, even with the added effect of increase in viscosity, causes a much lesser proportionate reduction in the rate of evaporation. For example, reduction of the water volume by 30% in the case of glycerol only leads to 17% reduction in evaporation rate. This may be due to non-volatile material transferring heat to water not in contact with the heating surface.

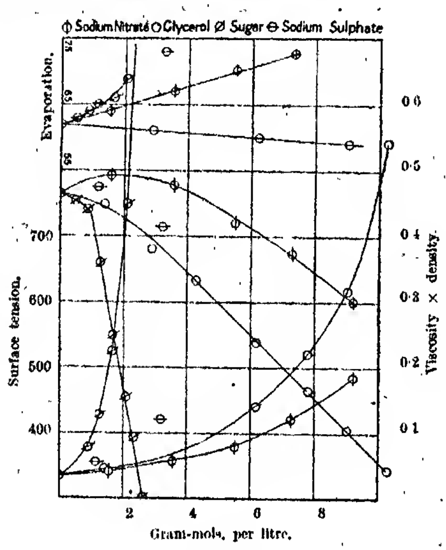

Fig. 4.

There seems to be little direct connexion between weight percentage and evaporation rate, except in so far as concentration change is connected with factors already discussed. The percentage composit[illegible] curves are included as they may have practical[illegible]orated

It is hoped to extend this work, but it [illegible]nd were concluded from the present results that [illegible]rding tension, volume percentage of water, and viscosity, are factors controlling rate of evaporation of solutions in tube evaporators, and that molar and percentage compositions are of less importance.

The author desires to thank Mr. E. Duus for carrying out some preliminary tests, and to acknowledge indebtedness to the Trustees of the Walter and Eliza Hall estate, who equipped the Industrial Chemistry Laboratory in which the work was carried out.

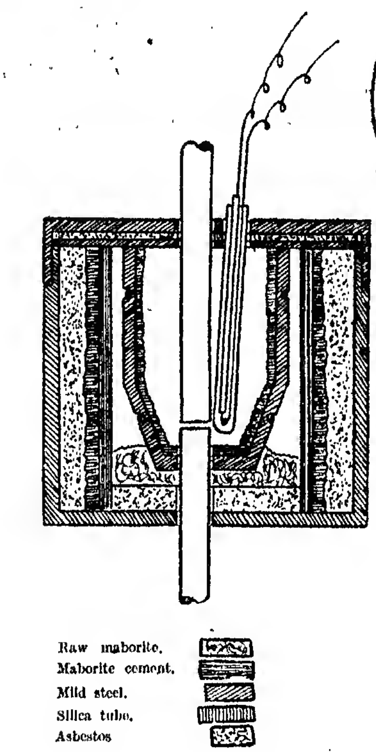
SOME PROPERTIES OF SOFT SOLDERED JOINTS.

BY T. B. CROW, M.SC., M.INST.MET.
(*Bowen Research Scholar in the University of Birmingham.*)

The operation of soft soldering is of such wide ndustrial application that it is surprising to find an .lmost complete absence of quantitative information n the subject. Much information[1] of a general haracter is available; this is, in most cases, concerned ither with the practical applications of the process r with formulæ for the preparation of solders and luxes. It does not appear that work has been done rith the objects of (1) examining in detail the effect f variations in the soldering conditions upon the esulting joins; (2) developing theories which will xplain the observed results; and (3) applying the iformation gained to the study of other soldering rocesses. A research with these objects in view has herefore been undertaken, and the following is a rief account of some of the results. The work is till in progress, and it is hoped that further informaion may be to hand in due course.

I. General.

In joining two metals or alloys by means of soft older, using flux and a soldering iron[2] or blow lamp, he following are the variable conditions:—(1) omposition of solder used. (2) Thickness of solder lm between the faces to be joined, and form of the in. (3) Nature of the metals to be soldered. l) Temperature of molten solder. (5) Initial condion, both physical and chemical, of the surfaces) be joined and of the mass of the metal beneath iose surfaces. (6) Length of time to which the metals re exposed to the molten solder. (7) Material used s a flux. (8) General manipulative procedure. (9) ther variables. In order to find out which combinaon of the above variables will give a join having the est mechanical properties, a very large number of ins was made under known variable conditions, ıd subsequently tested in tension and in shock. he general scheme of making a join was as follows: wo straight rods, made of the metal or alloy ıder examination and sufficiently long to enable ıe joins to be made and the tests carried out, ere firmly supported in a heavy cast iron stand o as to be vertical and co-axial) with their ends almost touching. Surrounding these ends was a crucible of such size as to contain more than enough molten solder to immerse them completely to a depth of not less than ½ inch, and also to contain the hot junction of a thermo-couple, suitably protected. The crucible itself was totally enclosed in an outer container, and the annular space thus formed was filled with asbestos lagging, and contained (in the shape of a resistance winding) the means of supplying the necessary heat to melt the solder and hold the work at any desired temperature for any length of time. The crucible was charged with a definite weight of solder in small pieces, together with a liberal amount of flux, and heated. The desired temperature above the melting point was maintained for a known period, and then the whole was allowed to cool until completely solidified. The constructional details of the furnace are shown in Fig. 1.



Sectional view of furnace etc. for making soft-soldered joins.

FIG. 1.

II. Variation of width of gap.

To investigate the effect of variation in the thickness of the solder film upon the tensile strength of the join, twenty-three joins were made (only nineteen of which were finally available for testing), with gaps varying from 0·2 to 5·1 mm., the following factors being kept constant throughout:—Soft solder of eutectic composition (Sn 62·93%, Pb 37·07%; m.p. 183·3°). High-conductivity copper rod, in a partially cold

[1] See bibliography at end of this paper.
[2] The expression "soldering iron" is conventional and will be adhered to throughout this account. A soldering copper is, of course, referred to.

worked state; ¼ in. diam. Faces "butt," and clean. Flux used, zinc chloride, in powder, and also as a thick water paste. Temperature of joining, 275° C. Time allowed at 275°, ten minutes. Table I. and Fig. 2

values are compared with the ordinary tensile strength of the materials which comprise the joined rod—namely, the solder and the copper—after bringing them by previous treatment to the same condition as if they had been treated in the joining process itself. From these tables it appears that:—

(1) The join having the thinnest film of solder in the gap is the strongest.
(2) The highest tensile strength obtained was less than the yield point of the copper.
(3) Elongation and yield points were only measurable with joins having a considerable thickness of solder in the gap.
(4) The strength of a join having 5·1 mm. of solder was substantially that of pure solder, although the yield point was higher.

III. Variation of joining temperature.

In this set of experiments, the film thickness was kept approximately constant between 0·1 and 0·15 mm., and joins were made at temperatures ranging between 230° and 415° C. The time allowed at the joining temperature was twenty minutes, and eutectic solder and zinc chloride were used as before. A different copper rod was used, and after treatment at 415° C. in the joining furnace, exactly as if it were being used in making a join, gave:—yield point, 23·4 tons per sq. in.; tensile strength, 25·0 tons per sq. in.; elongation (on 1 in.), 16%. The rates of

Tensile strength of joins compared with temperature.
FIG. 3.

heating and cooling were accelerated to suit the increasing joining temperatures by the use of suitably increased currents during heating and the

partial opening of the furnace top during cooling, so that a constant time was maintained between fusion and solidification of solder.

Several joins were made at temperatures considerably above 415° C., but these had to be abandoned, because so much copper rod had been dissolved by the "solder" as to make it impossible to prepare a satisfactory test piece from the resulting join. The shock tests were carried out with an Avery Izod impact machine. The plane of the join was coincident with that of the upper faces of the grips, which had been specially made to take a round specimen of $\frac{5}{16}$ in. diameter. An 11 ft.-lb. hammer was used, released from a position corresponding to a kinetic energy content of 1 ft.-lb. only, at the moment of impact. Table III. shows that all the specimens required only from 0·05 to 0·1 ft.-lb. to break them, irrespective of joining temperature. With a thicker solder film joins would probably give higher impact values, and work is in view upon this point.

The results of the tests in tension are set out in Table IV. and Fig. 3. The curve shows definitely

that under the conditions in which the experiments were made, a temperature of about 265° C. gives the strongest joins. Joins made between 230° and 280° were quite strong. Above this temperature there is a very definite falling off in strength from some 11 to about 5 tons per sq. inch.

IV. Action of flux.

A few preliminary experiments were made to ascertain the action of flux (zinc chloride) in soft soldering.

Samples of zinc chloride were heated to about 400° C. in the presence of (*a*) eutectic solder alone; (*b*) copper rod alone; (*c*) solder and copper together. Subsequent analysis revealed no change in the composition of the solder, and no trace of copper, tin, or lead in the flux. Since fused zinc chloride is a very active electrolyte, it is reasonable to assume that no electrochemical action will take place when resin, tallow, etc. are used as fluxes.

If it is assumed that, apart from any physical action, the action of zinc chloride in soldering is simply to prevent chemically clean surfaces from becoming oxidised, or to remove any oxide which may be there to begin with, then if joins are made:—(1) with clean copper, using flux; (2) with copper, having oxidised surfaces, using flux; (3) with copper, with chemically clean surfaces, using no flux, but carrying out the operation in a non-oxidising atmosphere, and keeping other conditions constant in each case, such joins ought all to be equally found in mechanical properties. That this was substantially true will be seen from the results of Table V., from which it appears that chemically clean metallic surfaces can be satisfactorily soldered without the use of flux

* Owing to the cooling action of the stream of CO_2, a temperature some 10° higher was used

V. Microstructure of joins.

A number of joins were made at temperatures ranging between 237° and 497° C., and submitted to micro-examination. The specimens were so cut as to enable the excess of solder around the join to be examined, as well as the join itself, and polished on selvyt cloth, using "Silvo" metal polish. With this treatment the whole of the structure could be shown up faintly without the use of an etching reagent. A freshly made 10% solution of ammonium persulphate was frequently used, however, which darkened the solder and any free lead that was present, but which (owing to protective electrochemical action) developed no structure upon the cupriferous materials present. The following is a brief *résumé* of the results:—

(1) *Joins made between 237° and 293° C.*—The bounding line between the unchanged copper and the other constituents was extremely well defined. This boundary probably is not a sectional view of the original end of the copper rod, but appears to represent the furthest point to which diffusion has proceeded into the copper. In the centre portion of the join and occupying the greater part of the

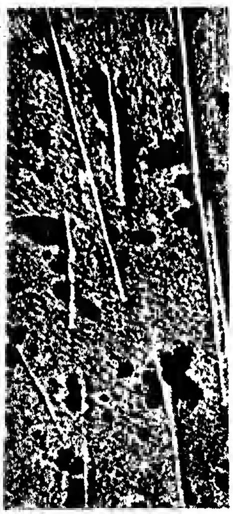
Joined at 260° C. × 400.
FIG. 4.

Half-join at 340° C. × 400.
FIG. 5.

gap is a band of eutectic solder having the typical structure. Between this and the copper boundary above referred to is a layer of a greyish material, and adjoining this, on the side nearest the solder, but scarcely visible, is a black fringe (see Fig. 4).

(2) *Joins made between* 325° *and* 360° *C* were similar to those described above, except that immediately adjacent to the copper, and between it and the grey layer, was a blue band. Also the black fringe was more decided and, as temperature increased, there were increasing numbers of black globules in the general solder mass on the sides of the joined rod (see Fig. 5, which shows *one* half the join only).

(3) *Joins made between* 402° *and* 497° *C.*—In these cases the solder mass around the join (and also the join itself, to a small extent) contained large numbers of long needle-shaped crystals white at the edges, but mauve in the interior. It was noticed that in these joins considerable solution of the copper had taken place, leaving an unaltered portion of rod of considerably reduced diameter (see Figs. 6 and 7, which show the needles and dark globules



Joined at 497° C. × 50.
FIG. 6.

Joined at 497° C. × 200.
FIG. 7.

at low and at high magnification respectively). If it is assumed that these needles crystallise out at a temperature above the general solidifying point of the solder, then their presence in the actual gap would prevent the copper ends being brought close together. The result would show as a thick film of solder in the gap, and is well illustrated in Fig. 9, which shows sections of two joins, made at temperatures of 265° and 497° C. The extent of the solution of the copper rod in the case of the high-temperature join will be noted.

It may be concluded that at moderate temperatures the tin of the solder diffuses into the solid copper forming a grey tin-copper alloy, leaving an excess of lead which separates out as a thin black fringe. At higher temperatures, the diffusion is more rapid and more extensive, forming, in addition to the grey material, a blue one, which is probably richer in copper. Much lead will, in consequence, separate, and this is seen as a thicker black fringe, or in globules, according to the amount. At higher temperatures still, copper is dissolved by the tin, and needle-shaped crystals of duplex composition separate out on cooling. It would appear that the blue alloy is connected with the falling off in tensile strength of the joins in which it occurs, as shown from Fig. 3.

To ascertain whether the "blue" and "grey" alloys were of constant or gradually changing composition proceeding outwards towards the copper itself, and also, if possible, to gain some information as to their composition, copper rods were allowed to "soak" in molten solder, of eutectic composition, at definite temperatures for $1\frac{1}{2}$ hours and allowed to solidify *in situ*. Four experiments were performed, two at 250° and two at 435° C, corresponding to the temperatures of formation of the grey and blue constituents, respectively. One specimen from each set was cut through longitudinally on a diameter of the rod and examined microscopically. Diffusion was found to be quite insufficient to permit of a layer of any particular constituent being turned off and analysed. Scratch hardness tests showed appreciably different values as the various bands were crossed. Scratch widths were:—copper, 0·42 mm.; solder, 0·55 mm.; grey constituent, 0·34 mm.; blue constituent, 0·21 mm. The "blob" of solder around the two remaining specimens was analysed, samples being taken from such portions as would be uncontaminated with the diffusion products immediately adjoining the rod itself. At 250° no copper was present, but at 435° C, 8·9 and 4·05% of copper was found in the top and bottom portions of the "blob" respectively, indicating that segregation of the needle-shaped mauve crystals to the top had taken place. The experiments just described are not conclusive but indicate lines of procedure for future work.

SOME PROPERTIES OF SOFT SOLDERED JOINTS.

BY T. B. CROW, M.SC., M.INST.MET.

(*Continued from p.* 68 T.)

The observations recorded suggested the possibility of squeezing out all the solder in the gap and of obtaining what would really amount to an autogenous welding of the layers of the grey material. Whether this can be done or not will depend upon two factors at least, namely: (1) the extent to which the surfaces to be joined approach a true plane surface, and (2) the nearness to which the welding temperature of the grey constituent is approached. In all the experiments already described, the upper half of the rod was pushed down upon its partner, and twisted to and fro at the end of the ten or twenty minutes steady period. The process was repeated at 200° C. Contraction between 200° and the melting point would cause a gap which would fill with solder. If, therefore, the rods were pushed together at a temperature of (say) 1° above the melting point, the gap ought to be considerably reduced and all the solder squeezed out. A photomicrograph of such a join is shown in Fig. 8. It will be seen, when compared with Fig. 4, that the gap has been reduced considerably, and although union between grey layers has not been effected, nor the solder entirely squeezed out, a repetition of the experiment with more accurately faced up rods and a suitable temperature might lead to more positive results. The tensile strength of such close joins as above prepared showed no increase over that of ordinary joins.

VI. Fracture.

The interesting point arises as to exactly where the join fractures, *i.e.*, whether in the mass of a constituent or at a junction of two constituents. The fracture of joins of Section III. showed (with unaided vision) no coppery appearance, but consisted of two well-defined areas—a dull and a moderately bright

portion. Corresponding portions of the fracture in each half of the test piece were bright and dull, indicating that fracture took place at the surface of separation of solder and grey material. Also fracture

FIG. 15.

extended across the eutectic solder to a similar place on the other side. This is shown in Fig. 10, which is typical of a join containing no blue constituent. Figs. 12–15 illustrate fractures of joins made at increasing temperatures, in which the gradual change in the character of fracture will be noted, increasing areas of stony appearance (typical of Cu_3Sn) being seen with increase of temperature. In fact, in the case of high-temperature joins, fracture largely occurred in the blue material itself, but also partly at the separation of blue and grey constituents. This is shown in Fig. 11.

VII. *Conclusions etc.*

(1) The tensile strength of joins increases with diminution of thickness of solder film in the join. Tensile strength of all joins was less than the yield point of the copper, but the strongest join had a tensile strength of some 2½ times that of the solder.

(2) Where a constant thickness of solder film of 0·1 to 0·15 mm. was maintained, joins made at 265° C. were the strongest in tension; those made at temperatures appreciably higher than 280° C. were considerably weaker, a brittle constituent being observable. Joins made at different temperatures were equally weak under impact.

(3) The action of zinc chloride is to prevent oxidation by preventing access of oxygen, or to dissolve oxide if it is there at the start. It has no electrochemical action. Joins made on clean copper surfaces, in carbon dioxide, without using flux, were of normal tensile strength.

(4) Diffusion of the tin of the solder into solid copper takes place, giving micro-constituents which are grey or blue according to the temperature. At temperatures up to 360° C. little or no solution of the copper takes place, but at 435° C. it is quite rapid. Scratch hardness tests showed the blue constituent to be the harder.

(5) Fracture of tensile bars took place at the junction of the grey material and the solder in the case of low-temperature joins. In high-temperature joins fracture occurred partly in the blue constituent itself and partly at its junction with the grey.

Work is still in progress or in view upon the general lines indicated at the beginning of this paper and also upon various special points mentioned.

In conclusion the author wishes to express his appreciation of the kindness of Dr. W. E. Sumpner, Principal of the Municipal Technical School, Birmingham, for permission to carry out work in the Metallurgical Department; of Prof. Turner, Messrs. D. H. Ingall, Joseph Lones, and W. E. Thorneycroft for helpful assistance, and of Messrs. W. R. Barclay, W. H. Tait, C. C. Bamford, and Dr. R. S. Hutton for their assistance in the supply of suitable materials.

AN APPARATUS FOR THE ACCURATE VOLUMETRIC DETERMINATION OF TIN IN CANNED FOODS.

BY E. J. B. WILLEY, B.SC.

The increasing use of foodstuffs packed in hermetically sealed tinplate containers has led to the serious consideration upon the part of the Public Health Authorities of the possible dangers arising out of the almost invariable absorption which takes place of tin and other metals from the can, and subsequent ingestion of the contaminating metallic compounds. This has, in turn, directed attention to the various gravimetric and volumetric processes which have been proposed for the determination of tin in small amounts.

Of the gravimetric methods the consensus of opinion would appear to indicate that the most satisfactory determination of tin is afforded by igniting the foodstuff with sulphuric acid and (in small quantities at a time) nitric acid, addition of alkali

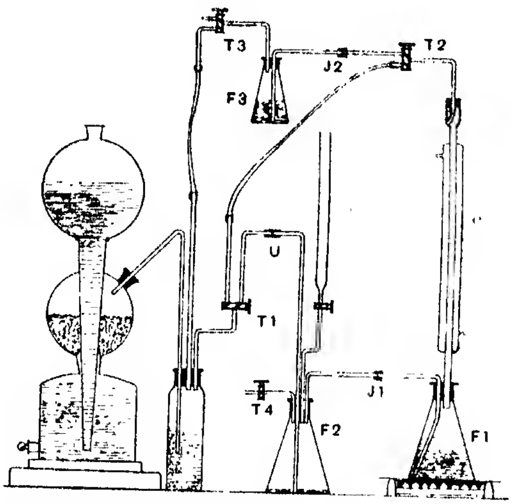
to give a solution of about 2% acidity (after boiling off any remaining nitric acid), precipitation of the tin as sulphide with hydrogen sulphide, followed by treatment of the filtered precipitate with dilute sodium hydroxide and re-precipitation of the tin sulphide from the alkaline solution with acetic acid. The sulphide precipitate is allowed to stand until it has settled, and is finally ignited and weighed as stannic oxide. The principal disadvantage of this method is that in dealing with small amounts of tin it becomes necessary to take a large quantity of foodstuff (say 100 g.) in the first place, in order to reduce any error in the final weighing of the few milligrams of stannic oxide which are obtained, thus lengthening greatly the initial ignition. Again, the re-precipitated tin sulphide may often take a long time to settle and this lengthens the determination still more. There is also the danger, in the case of foodstuffs containing more than the usual amounts of silica, calcium salts, or phosphates, of the tin sulphide precipitate being contaminated with quantities of these substances; the silica in particular, being appreciably soluble in dilute alkali, is dissolved and is precipitated with the tin sulphide. This has, upon a few occasions, been experienced in this laboratory.

On the other hand if appropriate steps are taken to guard against these possible errors, such as a second re-precipitation of the tin sulphide or, in doubtful cases, treatment of the stannic oxide precipitate with hydrofluoric acid after ignition in a platinum crucible, the method is capable of extremely high accuracy.

The volumetric methods for determining tin depend upon the reduction of the tin to stannous chloride and its subsequent titration, either directly or indirectly, with an oxidising agent such as iodine, potassium permanganate, ferric chloride, etc. The first named is most generally used. These, while excellent *per se* and capable of giving accurate results under very carefully controlled experimental conditions, suffer as laboratory processes from the great difficulty which is experienced in obtaining a quantitative reduction of the tin to the bivalent condition, largely owing to the ease with which re-oxidation takes place. Low results are, in consequence, obtained.

That the oxidation of the stannous salt prior to titration is recognised as the principal source of error in an otherwise accurate and convenient method for determining tin, is shown by the directions to be found in almost all of the published processes for preventing access of air to the reduced solution, and Sellars has designed an apparatus to obviate this difficulty (*cf.* Scott, "Standard Methods of Chemical Analysis," 1918). His device has not, however, been found to be impeccable when applied to the determination of very small quantities of tin such as are usually present in canned goods, or when tested against pure tin salts using the gravimetric process as the standard. On the other hand, the tin may be directly determined in the group II. precipitate by means of iodine, since no substances capable of interfering with the subsequent titration are likely to be present in more than traces.

In the apparatus to be described, the whole of the operations of reduction and subsequent titration are carried out under slight pressure and in an atmosphere of carbon dioxide. Back-oxidation thus being rendered practically impossible, the determination may be carried out upon a much smaller sample owing to the decreased error factor, and by its use the author has obtained results agreeing very closely with those obtained gravimetrically from a larger sample.



A Kipp apparatus, arranged to give a supply of carbon dioxide from marble and hydrochloric acid, is connected as shown to a wash-bottle containing lead acetate solution and packed with small pieces of broken glass. This has been found to give an extremely efficient gas-washing arrangement. A two-way tap, T1, fitted to the rubber stopper of this wash-bottle, is connected *via* the stout pressure tubing union, U, to the 300-c.c. Erlenmeyer flask, F2, and by a second piece of pressure tubing to the second two-way tap, T2.

Connexion between the wash-bottle and the third two-way tap, T3, is also provided, as shown, by a piece of pressure tubing. The Erlenmeyer flask, F2, is fitted with a stopper bored to take four tubes, viz. (1) that from the Kipp wash-bottle; (2) that leading *via* the ground joint, J1, to a second 300-c.c. wide-necked conical flask, F1, which is supported over an iron plate above a gas ring; (3) the tip of the burette tap; and (4) the small tap, T4. In the determination F2 is immersed in a white glazed pneumatic trough containing cold water.

The flask, F1, carries the condenser, C, and the delivery tube from F2. To the top of the condenser (double-surface type) is fitted a rubber stopper carrying the two-way tap, T2. One branch of T2 is connected *via* the ground joint, J2, to a third 300-c.c. flask (supported by a clamp from the retort stand which holds the condenser, C) and the other to the second branch of T1. Finally a third tap, T3, is provided in the stopper of F3 and one

branch is connected as already mentioned to the wash-bottle whilst the other is arranged to communicate with the atmosphere.

The determination of tin in canned foods is effected by the use of the apparatus as follows :— A 25-gram sample is ignited as for the gravimetric process and the tin is precipitated as sulphide in the usual manner. The precipitate is filtered off at the pump by means of an asbestos pad supported by a perforated disc. The washed pad of asbestos and precipitate are transferred to a 200-c.c. conical flask, 10 c.c. of hydrochloric acid, 0·25 g. of potassium chlorate, and 75 c.c. of water are added, and the whole is boiled vigorously for 15 min. to dissolve the tin and oxidise any sulphur which may be present. The solution is then filtered, transferred to a wide-necked flask of the type already mentioned, and boiled again with the addition of a further 3 c.c. of hydrochloric acid to decompose any remaining chlorate and also to expel chlorine etc. Boiling is allowed to proceed until the volume of the solution is about 20 c.c., when it is stopped ; 10 c.c. of starch solution are then placed in F2, the stopper is placed in position, and the pressure tubing · union, U, connected up. A piece of zinc foil about 4½ by 2 in. and weighing some 3 g., is placed in the flask containing the tin solution (F1) and 20 c.c. of strong hydrochloric acid are added. F1 is placed in position on the hot plate above the gas ring, the joint, J1, is connected, and a rapid current of carbon dioxide from the Kipp sent through the apparatus to expel most of the air, T1 being turned to allow passage of the gas through F2, F1, up the condenser, and to atmosphere *via* T2, which should not yet be connected to F3. After two or three minutes, 50 c.c. of freshly boiled water are placed in F3, T3 is opened to atmosphere, and J2 connected up so that the carbon dioxide now bubbles through the water in F3 and out to atmosphere. The gas current is then diminished so that about two bubbles per second pass through the wash-bottle, and the gas ring is lit to heat the solution in F1, which is then boiled gently for 30–35 min., a slow current of carbon dioxide being maintained as before At the end of this time the gas is turned off and T3 shut off entirely for about a minute. T1 and T2 are then reversed to apply the carbon dioxide pressure to the top of the condenser so that the liquid in F1 is forced up the tube connecting F2 and F1 and into the starch solution in the first-named flask, T4 being opened to allow the displaced carbon dioxide in F2 to escape. When all the solution has run into F2, T4 is closed and T1 shut off entirely. T2 is then brought to its original position (*i.e.*, giving connexion between the condenser and F3) and T3 is reversed to allow carbon dioxide from the Kipp apparatus to enter F3 above the water surface and thus to force the liquid through T2 to the condenser and into F1.

The carbon dioxide in F2, having been somewhat heated at first when the solution from F1 was blown into the flask, will now contract due to cooling taking place, and this, together with the carbon dioxide pressure, will force the rinsing water into F2, thus removing the last traces of stannous chloride solution from F1. When F1 is again empty, T1, T2, T3 are opened to allow carbon dioxide to pass through the apparatus as in the reduction and in a rapid stream to mix and cool the solution in F2. The gas is allowed to run for two minutes or so if necessary, but the author has found that the liquid in F2 is usually cool enough to be titrated when all the wash-water from F3 has been blown into it. Iodine is then run in from the burette until a permanent blue coloration is obtained, the current of carbon dioxide keeping the solution in a state of agitation. In his determinations the author uses $N/200$ iodine, in which case for a 25-g. sample the percentage of tin is obtained by substituting in the formula, c.c. of iodine used × correction factor 118·7 ÷ 100,000.

The apparatus has for some time now been in use in this laboratory, where numbers of routine determinations of tin are made, and has given excellent results. For example, to two samples of a meat preparation known to be free from tin a solution containing the equivalent of 0·00957 g. Sn was added. The result by the gravimetric method (mean of two) was 0·00957 g. Sn, and by the volumetric method using the above apparatus, 0·00958 g. Sn.

The time required for a determination of tin by this method, inclusive of the ignition period, is about six hours.

The author's acknowledgments are due to Messrs. Angus Watson and Co., Ltd., in whose chemical laboratory the above apparatus was designed and tested, and to Mr. H. Pearman for the sketch which illustrates this description.

THE CORROSION OF MUNTZ METAL IN SEA WATER.

BY W. DONOVAN, M.SC., AND T. E. PERKS.

In 1918 the Public Works Department, New Zealand, experienced trouble with some Muntz metal sheathing on Otaika Bridge, owing to its rapid disintegration, and asked for an investigation into the cause of the occasional rapid corrosion of this metal in sea water. It was suggested that slight differences in the chemical composition might account for differences in the resistance of the metal to the action of the sea water.

To facilitate the investigation, the following twelve samples were submitted :—

1 and 2. Disintegrated within two years on Otaika Bridge, above low water. (Brackish.)

3. Seven years in position, Kioreroa Bridge.

4. In position since 1915. (Locality not stated.)

5. New metal now being used.

6. Metal supplied in 1916 and unused.

7 and 8. Seven years in position, Kioreroa Bridge.

9. In position on Wool Wharf, Wellington, from 1880 to 1912.

10. In position since 1863, Queen's Wharf, Wellington.

11. New metal received within the last two years. (P. H. Muntz and Co.)

12. In position for 25–30 years, Opua Wharf, North Auckland.

These gave the following results on analysis :—

Sample no.	Cu.	Zn.	Pb.	Sn.	Fe.	As.
1	69·67	29·53	0·47	0·25	0·16	Undet.
2	67·15	31·84	0·82	0·20	0·13	Undet.
3	60·44	38·41	1·06	0·10	0·14	0·05
4	64·22	35·82	0·48	0·16	0·13	0·06
5	60·90	37·64	1·07	0·05	0·16	0·05
6	60·12	38·51	0·90	0·33	0·12	0·18
7	60·12	38·59	1·20	0·08	0·11	0·04
8	65·36	34·28	0·30	0·10	0·03	0·06
9	61·30	37·76	0·57	0·13	0·10	0·05
10	61·46	37·79	0·47	0·07	0·08	0·05
11	61·00	37·87	0·70	0·16	0·12	0·09
12	61·56	37·60	0·73	0·08	0·05	0·05

The manganese in all the samples is less than 0·01%.

It is evident from the table that in addition to Nos. 1 and 2, which were practically disintegrated, the copper content of Nos. 4 and 8 was higher and the zinc less than in unused metal, indicating corrosion by loss of zinc (with apparent enrichment of the copper). The comparative brittleness of these samples and their appearance under the microscope gave confirmatory evidence of this.

The samples may be divided into four classes :—

(1) Unused metal, of recent manufacture (Nos. 5, 6, 11).

(2) Corroded metal (presumably of recent manufacture) (Nos. 1, 2, 4, 8).

(3) Good quality metal, in use 7 years (Nos. 3, 7).

(4) Good quality metal, in use 25 years and over (Nos. 9, 10, 12).

Apart from the copper and zinc content, there is apparently no relation between the chemical composition of the metals examined and their corrodibility.

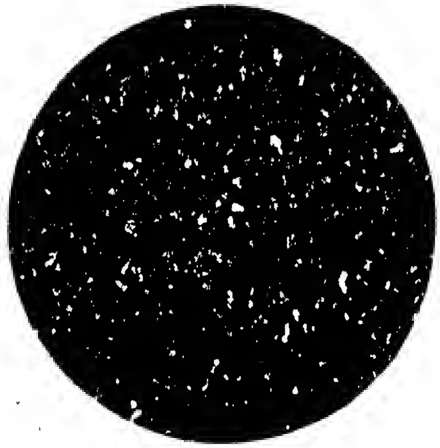
Micrographical examination.

The samples were submitted to micrographical examination, with a magnification in all cases of 80 diameters and oblique illumination, after polishing in such a manner as to reduce cutting, overheating, and surface flow to a minimum. The etching reagent finally adopted was ferric chloride and hydrochloric acid (Desch, "Metallography," 1910 edition, p. 147), all samples being "developed" in a photographic dish at the same time so as to obtain equal periods of etching in a standard solution.

Heat-treatment of sheathing.—A study of Shepherd's constitutional diagram of the zinc-copper alloys in conjunction with the remarks of Rosenhain ("Introduction to Study of Physical Metallurgy") on the subject, suggested the heat treatment of sheathing with a view of observing the manner in which the α and β phases varied at different temperatures. A small sample of finely crystalline Muntz metal sheathing was taken and portions were subjected to various temperatures for one hour and then quickly cooled, polished, and etched, with the results shown in Figs. 1 and 4.

Fig. 1 illustrates the untreated Muntz metal, showing both α and β phases, the α phase predominating. Samples heated to 400° and 500° C. differed so little from the untreated metal that their photomicrographs are not included.

Fig. 2 shows the result of heating to 600° C. It will be noticed that there is here a critical stage in



Untreated. × 80

FIG. 1.

600° C. × 80

FIG. 2.

which neither α nor β is dominant, each tending to merge with the other. In future an alloy in which this change $\alpha \rightleftarrows \beta$ appears will be referred to as being in a state of "transition."

Fig. 3 shows the sample after having been heated to 700° C. for one hour. The β phase predominates and α is intercrystalline. For simplicity the phase which preponderates will be termed the "dominant phase."

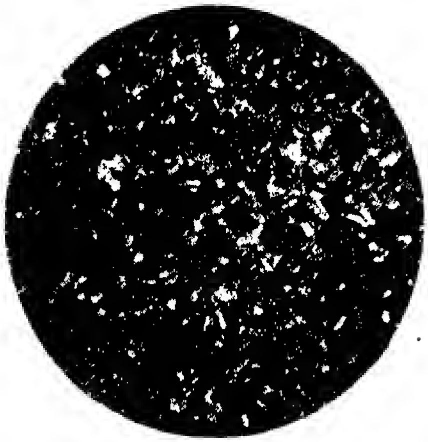
Fig. 4 shows the almost complete conversion of the sample to pure β as a result of heating to 800° C., the intercrystalline α being in very small amount.

These results were confirmed by the treatment of a variety of sheathings ; they show the manner in which heat treatment affects the constitution

of the alloy and indicate that the heat treatment to which a Muntz metal has been subjected may be determined by a study of its microstructure.

The microstructure of samples 1 to 12 (Table I.) will now be considered.

Sample 1 (Fig. 5) and *Sample* 2.—Here the dominant phase was α with intercrystalline β. So badly disintegrated were these alloys within two years' service that the selection of a representative area was difficult; coppery patches will be observed on both sides of the photograph. The porosity of the metal would either indicate overheating and volatilisation of zinc in patches during manufacture, or unusually severe conditions of usage.*



700° C. × 80

FIG. 3.

800° C. × 80

FIG. 4.

Sample 3.—α was dominant with β intercrystalline and in small proportions (as Fig. 1).

* This is referred to in the accompanying paper, "The Corrosive Action of Brackish Water on Metals," by T. E. Perks.

Sample 4 was quite brittle. It consisted of a moderately large amount of intercrystalline β with large corroded α crystals.

Sample 5 (new metal) consisted of α crystals dominant, with a considerable amount of intercrystalline β. The solution of this β phase will hasten exfoliation of the α crystals and the alloy cannot be considered a good one.

Sample 6 resembled sample 5, but exfoliation will probably be more rapid. Probably this sample was manufactured too hastily, rapid cooling from a rather high temperature giving too high a proportion of β.

Sample 7.—The dominant phase was α, while the intercrystalline β did not completely isolate α crystals, as with samples 1, 2, 5, and 6.

Sample 8 was quite brittle and consisted of dominant β with intercrystalline α.

Sample 9 (32 years' service) consisted of dominant α, uniform and finely crystalline. Exfoliation a minimum.

Corroded metal. × 80

FIG. 5.

Sample 10 (49 years' service) consisted wholly of the transition stage (Fig. 2). Electrolytic action between the α and β phases would be negligible and also exfoliation.

Sample 11 (new metal) was identical with sample 9.

Sample 12 (25–30 years' service) was very similar to samples 9 and 11.

From this point the investigation was continued into a further series of Muntz metal bolts and sheathings; the results obtained generally confirmed those given above.

In all bolts which had corroded there existed a central core of unaltered Muntz metal surrounded by a shell of the coppery coloured, corroded portion. Such corrosion renders the threads of bolts extremely brittle and may even extend completely through the bolt, causing it to snap under strain. The depth of corrosion generally depended on the duration of immersion.

The authors have found great variation in the character and proportion of the phases present in numerous samples of Muntz metal bolts and sheathing. Indeed, uniformity in manufacture would appear to be by no means the rule. Whether the α or β phase is dominant will depend solely upon the heat treatment of the alloy during manufacture, and it seems probable that sufficient scientific control of the product is not adopted. Bengough and Hudson state (J., 1909, 657) that, in order to put the metal on the market in its best possible physical condition, particular attention should be paid to its final rate of cooling.

The authors have noticed that, in Muntz metal manufactured many years ago, so far as their observations have gone, either α and β merges into the other (transition stage) or α is dominant with β in minor proportions. Such a product has received thorough annealing at a low temperature with gradual cooling, thereby ensuring the reduction of the proportion of β present in favour of α. It seems probable that the minor proportion of β ound in the resistant samples, while not sufficient o cause marked exfoliation of the dominant α rystals, will by being first attacked (Desch, J., 1915, 260), protect these from immediate corrosion. The conversion at 470° C. of the α into $\alpha+\gamma$ as lescribed by H. C. H. Carpenter (J., 1912, 133) vould still further reduce the proportion of β present nd so tend to produce a more resistant alloy.

Of many modern samples of Muntz metal examined he dominant phase is too commonly β, or, if not hat, the proportion of β present is so high as to solate α crystals from one another and cause rapid isintegration. Mathewson and Thalheimer (J., 1916, 064) recommended for a 61% brass, a cooling ate of 20° C. per minute down to quenching at 50° C.; for 61—63% brass, a rate of only 5° C. own to quenching at 550° C. is preferable. Similrly with Muntz metal, for the best results the rate f cooling should be slow.

Apparently the manufacturer to-day hastens production and produces an alloy high in β by treating t too high a temperature and pickling too suddenly, ving the growth $\alpha \rightarrow \beta$ no time to develop. We elieve that this is a more adequate explanation of ie inferior quality of some Muntz metals manuctured of recent years than that it is due to the e of electrolytic copper instead of the less pure nelted copper.

The following tabulation of the examination of me thirty samples (bolts and sheathing) of used untz metal gives the relationship between the ase which predominates and the corrodibility of e alloy :—

Dominant phase.	Condition.	Period of use.	Number of samples.
α	Good	12–58 years	12
β	Bad	5–25 years	15
nsition	Good	39–57 years	3

Summary.

So far as they go, these results tend to show at :—

1. Dominant β always results in rapid corrosion. is confirms the work of Bruhl, who found that the effect of high temperatures of annealing followed by quenching and rolling was to increase the rate of corrosion (J., 1911, 1164). In the alloy produced in this way β predominates. Desch has also noted the preferential corrosion of the β phase (J., 1915, 260).

2. Dominant α is very resistant if the proportion of β is insufficient to hasten exfoliation.

3. The transition stage is the least corrodible, probably because electrolytic action between the α and β phases will be a minimum in such an alloy.

Wellington, N. Z.

THE CORROSIVE ACTION OF BRACKISH WATERS ON METALS.

BY T. E. PERKS.

In a paper on the corrosion of Muntz metal by W. Donovan and T. E. Perks (p. 72T), dealing with the relation between the micro-structure of Muntz metal and its "corrodibility" or resistance to corrosion, it was shown that, in general, where the β phase was intercrystalline and in small proportions, the alloy had for many years withstood the action of sea water without marked deterioration. Where the metal consisted of α crystals with a large proportion of intercrystalline β, which would cause exfoliation of the α crystals, rapid corrosion had taken place. It would hardly be predicted, however, that the alloy, not constitutionally sound, would completely disintegrate within two years of service, and it became evident that some other factor in corrosion was to be looked for. Enquiry showed that the two samples (*loc. cit.*, Nos. 1 and 2) had been subjected to the action of the brackish waters of a tidal river where no contamination by sewage or by factory wastes would occur. The excessively corrosive action of brackish waters has been known for many years, and it was suggested by the Corrosion Committee (J., 1916, 471) that the dilution of salt with fresh water, by giving rise to greater ionic dissociation, increased the attack upon a metal immersed in the mixture. This assumption seems hardly adequate to explain such rapid corrosion, and the following theory is now advanced (which will be called the "theory of varying salinity").

It is an established fact that a difference of potential exists between two solutions of the same salt of different concentration; suitable connexions being made, an electric current will flow through the circuit. From this fact it was assumed that, in the case of estuarine waters, where at frequent times the fresh water flows over the salt, the water would be found to be in layers of varying salinity. This being so, a sheet of Muntz metal (ensheathing a wooden pile, for example), exposed to these layers of varying saltness, would establish the necessary circuit and an electric current would flow through the metal. Milton and Larke (Proc. Inst. Civ. Eng.,

1903, 154) have shown, by experiments with an applied electric current, that electrolytic action alone, even with exceedingly minute currents, may result in severe corrosion or decay. This would greatly hasten corrosion and thus explain the excessively corrosive action of brackish waters. Before taking samples of tidal river waters, some experiments were made to demonstrate this action. Two polished strips of Muntz metal, one placed in a porous pot containing salt water of a concentration about equal to that of sea water (approximately 3% NaCl) and the other in very slightly salt water surrounding the pot, developed a difference of potential varying from 9 to 16 millivolts. These strips when both immersed in the same salt solution showed no difference of potential. After experimenting thus in a variety of ways it became apparent that a quite easily measurable current would be established through a Muntz metal sheet immersed in brackish water. It may be pointed out that in tidal rivers the water is seldom, if ever, uniformly brackish.

past the metal and that brackish water in layers of varying salinity might be an important factor in corrosion.

The apparatus was then used to test the corrodibility of the first twelve samples described in the preceeding paper, all being immersed together and examined at regular intervals. The results showed the correctness of the statement previously made that samples rich in β or with predominant β are the more corrodible. For example, No. 11 withstood the test well, as did Nos. 9, 10, and 12, but Nos. 4, 5, 6, and 8 corroded rapidly. This further establishes the urgency of correct heat treatment.

These experiments suggested a possibility of comparing the corrodibility of samples by measuring the voltage developed by each under standard conditions. It was impossible to obtain consistent results either with a quadrant electrometer (which should have obviated complex polarisation effects), or with a high-resistance galvanometer, and it was found that the results could be varied by the manner in which the strips had been polished. Curves

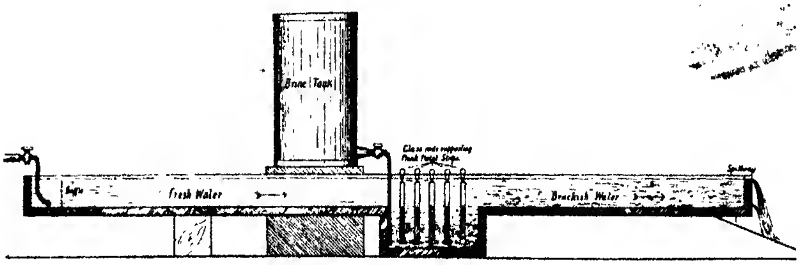

FIG. 1.

An attempt was then made to simulate the conditions found in tidal rivers. A wooden race (see Fig. 1) was constructed, six feet long, having an internal cross-section of 3 in. deep by 2 in. wide. Four feet from the inflow end was a brine pit, giving an additional depth of four inches. This pit was supplied with 3% solution of common salt from a cistern while the race was kept supplied with tap water at the rate of a litre per minute. At the brine pit, therefore, there was a layer of fresh water flowing over a layer of salt water of approximately the same strength as sea water. A sample of the water was taken at each inch of depth over the brine pit at frequent intervals; a typical reading expressed in c.c. of silver nitrate was as follows:—1 in. from surface, strength=0·1 c.c. $N/10$ $AgNO_3$; 2 in., 0·3 c.c.; 3 in., 0·7 c.c.; 4 in. 2·9 c.c.; 5 in. 3·6 c.c.; 6 in. 4·7 c.c. It will be seen that the definition between the salt and fresh layers was very sharp. Strips of polished Muntz metal were now suspended in the pit so that a portion of each was in the fresh and a portion in the salt water. In thirty minutes the corrosion was visible to the naked eye. Strips left in the salt solution alone for the same time showed no change. This experiment demonstrated that the electric current was not prevented by the flow of the water

showing rate of polarisation were also obtained which, while similar, bore no relation to the properties of the alloy observed in practice. Further experiment along these lines might succeed in producing intelligible results, but Desch has pointed out the difficulty of such a task (J., 1915, 259).

It now remained to sample the waters of a tidal river at various depths. This was done at the mouth of the Hutt River, which empties into Wellington harbour. The samples were taken at successive depths of 5 feet each, in a clean, dry bottle. Owing to the rise of a strong southerly wind blowing against the river it was necessary to remain three quarters of a mile off shore. One set of samples was taken here, the next set six fathoms nearer the shore. Immediately a sample was taken its temperature was observed and the chloride present determined in order to discover whether the boat was sufficiently near the river mouth and whether the rough weather had seriously interfered with the experiment. All samples were securely corked and both chlorides and oxygen present carefully determined in the laboratory. There was no variation in the oxygen present in successive samples and the figures are not included. The following results give the salinity at successive depths of five feet:—

Three quarters of a mile off shore.

Depth	Temperature	Chlorine calc. as sodium chloride.
Surface	12·00° C	1·7%
5 feet	12·25° C	2·1%
10 feet	13·50° C	2·6%
15 feet	13·00° C	2·8%
20 feet	13·00° C	2·9%
23 feet (bottom)	13·00° C	3·0%

Six fathoms nearer the river mouth.

Depth	Temperature	Chlorine calc. as sodium chloride.
Surface	12·00° C	1·5%
5 feet	12·00° C	1·7%
10 feet	12·50° C	2·6%
15 feet	12·75° C	2·7%
20 feet (bottom)	13·00° C	3·0%

These tables show that, despite the stormy weather, the waters are not uniformly intermingled, but are in fact in layers of varying salinity. Waters in such condition will, as already shown, exert a very corrosive action upon Muntz metal or, obviously, upon any other metal.

Fig. 2 incorporates these results and shows very clearly that a pile sheathed with Muntz metal and immersed between depths of five and ten feet would

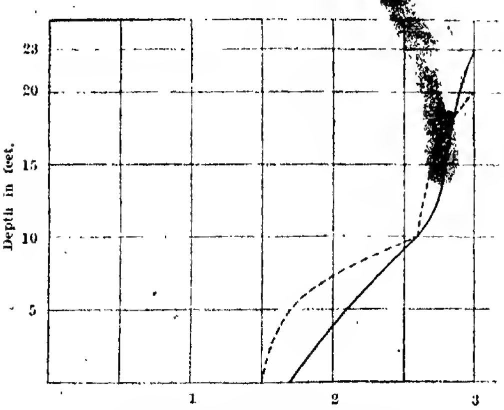

FIG. 2.

e, in these instances, subject to an appreciable otential difference between the top and bottom of the heet. It must also be emphasised that wherever alt and fresh waters mingle there will be no udden uniformity established and that currents, ayers, and eddies of water of varying salinity will xist. The author believes that this theory of rying salinity will help to explain the excessively rrosive action of the brackish water of tidal rivers of admixtures of sea water with the storm and her effluent waters of a seaport town.

The author is indebted to Dr. J. S. Maclaurin, Dominion Analyst, for permission to publish these esults; also to Mr. G. C. Burton, of this laboratory, or assistance in sampling the Hutt River water.

THE DETERMINATION OF CADMIUM IN SPELTER AND ZINC ORES.*

BY C. E. BARRS, A.I.C.

In the sale of spelter it is often stipulated that cadmium is not to be taken as zinc; also, if the metal is to be used for rolling into sheet, it is important that the cadmium content, as well as the other impurities present, should be known accurately. Since the separation of cadmium from zinc is usually attended with more or less difficulty, it was thought that a description of the following method, with results obtained, might be useful.

Method for spelter.

Ten grams of the carefully sampled metal are dissolved cautiously in 30 c.c. of nitric acid (d 1·420) and 100 c.c. of water. When all is dissolved it is diluted to 250 c.c. with warm water, and ammonia (d 0·880) added until the zinc hydroxide precipitate is redissolved; the solution is then heated to coagulate the remaining precipitate, which is filtered off and washed with a 5% solution of ammonia. Should the precipitate be very bulky it is as well to redissolve and reprecipitate it. The filtrate is then heated until nearly boiling, and whilst stirring, 2 c.c. of a 50% solution of sodium sulphide are added. The addition of sodium sulphide is repeated, with stirring, until a small excess of zinc is precipitated. The liquid is heated on a sand-bath for at least one hour, with occasional stirring, the precipitate filtered off without washing, and washed back into the same beaker, the filter cleaned with, and the precipitate dissolved in nitric acid; 15 c.c. of sulphuric acid (1 : 1) are added, and the mixture evaporated until sulphur trioxide fumes are evolved, when 25 c.c. of water are cautiously added, and heat is applied until all soluble salts have dissolved. When the mixture is cool, the precipitate is filtered off, and washed with 5% sulphuric acid, sufficient concentrated sulphuric acid is added to make the filtrate 20% acidity, and after warming to 60° C. hydrogen sulphide is passed for a few seconds to precipitate most, but not all of the copper. The liquid is gently heated, and the precipitate, when coagulated, is filtered off and washed with 2% sulphuric acid solution. (If the amount of copper is small it is preferable to precipitate it with the cadmium.)

The filtrate is then diluted to at least 250 c.c. with water, and hydrogen sulphide passed in until the precipitate settles out well. If after passing the gas for twenty minutes no precipitate has appeared, one or two drops of ammonia (1:1) may be added to facilitate the precipitation. The solution is filtered, and the precipitate washed with 2% sulphuric acid solution containing a little hydrogen sulphide, washed back into the same beaker, dissolved in a little nitric acid, evaporated if necessary, and filtered through the same filter paper into a large previously weighed silica crucible, and washed with 5% nitric acid. The contents of the crucible are then evaporated with 1 c.c. of sulphuric acid (1 : 1), ignited gently at first, then at a red heat, cooled in a desiccator, and weighed.

* Read at a meeting of the London Section on Jan. 7, 1924.

A few drops of nitric acid (1:1) and 3 c.c. of warm water are then added to the crucible, and heat is applied until any copper oxide has dissolved; the solution is titrated for copper by the iodide method in the usual manner. The result calculated to copper oxide (CuO) and deducted, together with the weight of the crucible, from the above weight = cadmium sulphate. The weight of cadmium sulphate multiplied by 0·5391 = cadmium.

Method for ores.

The finely-crushed ore (2–5 g.) is attacked with sufficient hydrochloric or nitric acid, or a mixture of both, to decompose it. The mixture is evaporated to complete dryness, treated with 25 c.c. of hydrochloric acid (1:1), and heated until all soluble matter has dissolved. The insoluble residue is filtered off and washed with 8% hydrochloric acid. The filtrate is neutralised with ammonia, and acidified with hydrochloric acid, so that there is 1 c.c. of acid per 100 c.c. of liquid; hydrogen sulphide is then passed until an excess of zinc sulphide is precipitated, after which the beaker is set aside in a warm place for one hour, with occasional stirring. The precipitate is filtered off and washed with 0·5% hydrochloric acid containing hydrogen sulphide, washed back into the same beaker, and dissolved in nitric acid, with the addition of a few drops of hydrochloric acid, if necessary. When dissolved, ammonia is added in slight excess the solution heated and sodium sulphide added, and the analysis proceeded with as in the spelter method

The spelter and ores used for this work already contained some cadmium, but additional weighed quantities of the latter, were added to the spelter and ores, when they were being dissolved. In the case of C, D, CI, and DI, further quantities of lead, iron, and copper were also added at the commencement of the analysis, in order to see what effect, if any, such impurities would have on the results. In C and D only one precipitation of iron was carried out.

Tin is very occasionally met with in spelter, and in view of this a small quantity of this metal was added in E and F, in addition to those impurities mentioned for C and D.

The results are tabulated below.

A special alloy of cadmium and spelter containing 0·395% of cadmium (prepared by Messrs. Locke, Lancaster and W. W. and R. Johnson and Sons, with special precautions against volatilisation losses), was also tested by the above method. The amount of cadmium found was 0·403% and 0·407%, whilst that found by their chemist using a different method of analysis was 0·390%.

	Spelter (Zn 99·8%) + cadmium.		Same spelter + 0·1 g. Pb, 0·05 g. Fe, 0·01 g. Cu, and cadmium.				Same, with addition of of 0·05 g. Sn.		Zinc ore (blende). Trials with 2 g.			Zinc ore (calcined calamine). Trials with 2 g.

THE SPONTANEOUS COMBUSTION OF COAL.*

BY J. IVOR GRAHAM.

The spontaneous combustion of coal is a serious roblem involving either directly or indirectly danger o life or limb, and also considerable financial loss. 'his latter is the case whether the phenomenon ccurs on the surface, underground, or amongst oal cargoes. The danger arising from the occurrence f spontaneous combustion underground was brought efore the public a few months ago by the serious xplosion which occurred at Maltby Main Colliery, s a result of which 27 men lost their lives during perations which were being carried out to save , considerable portion of the pit from complete loss hrough the spread of fires and heatings. The actual xplosion would appear to have been one of fire-amp, the explosive mixture becoming ignited at a re which was evidently burning in a more distant art of the workings. In the Cadeby disaster in 912, 35 persons lost their lives as a result of the rst explosion and 53 by the second—including three alued members of the Mines Inspectorate. The s of life through gassing and explosions resulting m spontaneous fires underground has been heavy, d the danger from this cause is likely to increase years go on, owing to the necessity for deeper ning under conditions of higher natural tempera-re and greater pressure on the strata above and low the underground workings. The dangers ising from spontaneous combustion at sea are ident. Heating of coal stacked on the surface at s works, coal wharfs, etc., is rarely responsible · casualties, since the direct danger of carbon noxide poisoning does not occur in the same way is the case in a confined atmosphere underground— even in ships' holds. In a "gassy" pit in addition re is the very serious aspect of a firedamp explo-n and/or a still more disastrous coal-dust explosion. the financial side the question of spontaneous mbustion assumes a most important aspect. seemingly small underground heating may cost colliery several hundreds of pounds. In many es large areas of coal are lost through a heating ving taken place sufficiently serious to necessitate complete sealing off of an underground district d abandonment of this for years, if not for ever. h occurrences have, unfortunately, been many the local coal field. The financial loss due to ntaneous combustion at sea is also very consider-le, and the casualties occurring on British ships ne have been given as between 50 and 100, with total annual shipping loss of 200 vessels. The estion of safe storage of coal on the surface is one considerable importance for gas-works and other industrial concerns where there is the necessity for storing large quantities of fuel.

Dudley (1665, *Metallum Martis*) refers to spontaneous combustion underground, and Plott (Professor of Chemistry, Oxford) in his *Natural History of Staffs*, 1686, describes in some detail the firing of coal, mentioning Dudley's work. The explanation of the phenomenon has been sought for many years by chemists, physicists, mining men, and others. The oxidation of pyrites—especially marcasite—was for long accepted as the main cause of spontaneous combustion (Plott); later, the absorption of oxygen by the coal or parts of the latter, bacterial action, and the oxidation of other inorganic material apart from pyrites have been put forward to explain the cause of heating. Berzelius concurred in Plott's view that pyrites is the responsible agency, and this idea prevailed until the middle of the 19th century, when De la Beche and Playfair (1846-50) discussed the causes of weathering and spontaneous combustion of coal, and suggested that in stacks fine coal is as likely to give trouble as pyrites. The pyrites theory appears to have been doubted by Percy (Chem. News, July 9, 1864), who definitely ascribed to coal the responsibility for spontaneous heating. A complete bibliography is not possible here, but mention should be made of the work of Richter (Dingl. Polyt. Journ., 1868, 1869, 1870, **190, 193**), who found that oxygen was absorbed by coal at first rapidly and later more slowly. He also discovered that coal can take up large quantities of carbon dioxide.

The next most important piece of work was carried out in 1879, by Fayol † who conducted experiments on a larger scale. His main conclusion concerning the stacking of coal was that it was necessary to exclude the coal from the action of air either by storage in air-tight vessels or immersion in water.

The general conclusions arrived at by Fayol from his experiments were that no rise of temperature occurs with a thin layer of slack, but that the temperature increases with the height of the heap (2 metres is safe). He also investigated the theory that spontaneous combustion was, to a certain extent, promoted by the presence of moisture, and came to the conclusion that "the influence of wet weather on the heating of heaps of coal has not been sufficiently marked to be observable."

In 1898 Dr. J. S. Haldane (Haldane and Meachem, Trans. Inst. Min. Eng., 1898, **16**, 457-492) carried out a very important investigation at Hanstead Colliery and in his laboratory at Oxford. He came to the conclusion that the rate of absorption of oxygen by coal varies with the percentage of oxygen

* Read at a meeting of the Birmingham Section on January 15, 1924.

† "Études sur l'Altération et la Combustion Spontanée de la Houille Exposée à l'Air." Bull. Soc. Ind. Minérale, 1879, II., **8**, [3], Paris.

D

in the air, that the rate of absorption of oxygen is doubled for every rise of 30° C., that this rate decreases as time goes on, and that the absorption takes place at the coal surface and does not penetrate deeply. Haldane was the first to observe the production of carbon monoxide during the oxidation of coal at ordinary laboratory temperatures, although underground this gas was absent in Hamstead Colliery—a result which has been confirmed by the present author.

Lewes in (1890 (J. Gas Light., **55**, 645) discussed at length the work of Percy, Richter, and others, and the influence of pyrites on spontaneous combustion. Lewes was not in full agreement with Richter regarding pyrites, believing that its function was to break up the coal during oxidation.

In 1909 Sir R. Threlfall (J., 1909, 759–773) gave a valuable digest of the findings of the Royal Commission which sat in New South Wales, 1896–1900, on "Ships carrying coals"

Since 1905 a considerable amount of work has been carried out, and an excellent publication by J. B. Porter, on "The weathering of coal," summarises the greater portion of work carried out up to the year 1914, including also a number of laboratory experiments carried out at McGill University, Montreal. The main factors then known to influence the spontaneous heating of coal were that oxygen is necessary for such heating, and that oxidation must take place under conditions such that the resulting heat cannot escape as rapidly as it is produced.

From 1908, onwards, considerably more attention appears to have been given to the subject by chemists. Dennstedt and Bünz (Z. angew. Chem., 1908, 1825–35) carried out a number of tests on different coals by passing a stream of oxygen over the powdered sample at temperatures of 135° C. and 150° C. These results indicated that their coals could be divided into four classes :—

(1.) Those coals in which the temperature never rises above that of the bath.
(2.) Coals which rise only slightly above the bath temperature.
(3.) Coals which rise fairly high, but will not ignite unless the oxygen supply is carefully increased with the rise in temperature.
(4.) Coals which ignite easily—as a rule in about 2 hours.

According to these investigators, self-ignition increases in a ratio corresponding to the amount of moisture in air-dry coal—which moisture they imply is water of constitution. They conclude that humic acids are formed as a result of oxidation and that these acids are exceedingly hygroscopic. They determined the Maumené value for their samples (*i.e.*, rise of temperature on mixing the dried coal with concentrated sulphuric acid) and also noted that the coals dried in a current of carbon dioxide gave a rise in temperature when mixed with cold water which was proportional to the increased liability to spontaneous ignition.

Boudouard (Compt. rend., 1908–9, **147**, **148**) discusses the production of ulmins during the weathering of coal and the connexion of the latter with loss in coking power (Rev. Mét., 1909, **6**, 446–458).

Dennstedt and Bünz concluded that neither the mineral constituents (pyrites) nor organic sulphur or nitrogen influence spontaneous combustion. They point out that this property depends on (1) the friability and (2) the moisture content of the coals. (Their work will be referred to again later.)

Parr and Kressman (Univ. of Illinois Bull. 46, 1910) carried out a number of tests in bins on Illinois coal, coming to the conclusion that in general pyrites masks the effect of oxidation of the coal substance. With regard to the latter they consider there is a critical temperature above which oxidation will proceed independent of external conditions until firing takes place.

Up to 1913 most of the laboratory researches in the oxidation of coal were concerned with the behaviour of coal at temperatures above 100° C. Such experiments carried out at elevated temperatures do not, however, throw a great deal of light on the actual course of spontaneous heating of coal.

Experiments were undertaken at the Doncaster Coal Owners' Laboratory in 1913 to trace the oxidation of various parts of the Barnsley Seam (which in South Yorkshire is very prone to take fire spontaneously) at temperatures varying from that existing normally underground (30° C.) in deep mines up to a temperature of 150° C. The results of these have been given in papers published in the Transactions of the Institute of Mining Engineers (1913 *et seq.*). In these tests the influence of pyrites was eliminated so far as possible by careful sampling of the coal and also by determination of the sulphate before and after oxidation.

TABLE I.

Comparison of rates of oxidation of the different portions of the Barnsley seam at various temperatures.

Absorption in c.c. at N.T.P. per 100 grams of sample

Experiments were carried out on the relative rates of oxidation in a current of air of the various portions into which the Barnsley seam could be easily separated. These include (in order of their position in the seam)—(1) top softs, (2) black shale from dirt band, (3) Barnsley hards, (4) Barnsley softs, (5) Jacks, and (6) cannel. Mother-of-coal, mineral charcoal, or fusain was also tested—this sample being taken from the top softs. The samples were tested for oxidation in the moist condition (water, 9-7%). In every case the rate of absorption was found to diminish rapidly with time.

The oxidation of these samples is of interest when looked at from the point of view of Stopes' classification (Proc. Roy. Soc., 1919, B90, 470) of the ingredients of coals—since the hard coal experimented with was identical with durain, whilst the Barnsley ... "top softs" were mostly composed of ... mixed with vitrain. The "top softs" probably contain rather more of the vitrain than the Barnsley softs. Table I shows the rate of absorption of oxygen at $1\frac{1}{2}$ or 2, 12, 48, and 96 hours respectively at the several temperatures, together with analyses showing ash and moisture content of these samples. The rate of absorption and total volume of oxygen taken up increase with rise of temperature. The form of the curve, however, was found to be much the same at the various temperatures examined.

The influence of fineness of division of coal was also tested. The rate of absorption, though increasing with fineness of division, was not found to be proportional to the mesh of sieve used. For example, the rate during the first 120 hours of oxidation of Barnsley hard coal of 30- to 60-mesh was on the average 80% of that of coal passing 200-mesh (Winmill, Trans. Inst. Min. Eng., 46, 563). Similar results were obtained by the present author for the influence of size on the relative amounts of various gases adsorbed by coal—indicating that the available surface of the particle is much greater than that calculated from external dimensions. It was evident that for practical purposes rates of absorption could be determined on samples sieved through a 60- or 90-mesh screen. The absorption of oxygen was found by Winmill to vary according to the equation

$$\text{Absorption} = K\sqrt{\text{partial pressure of oxygen.}}$$

From this equation it is evident that to prevent oxidation, the supply of oxygen would require to be completely stopped, *e.g.*, 5% of oxygen would still cause oxidation at half the rate of ordinary air.

One of the most important results of the Doncaster laboratory experiments was Winmill's determination of the heat produced during oxidation. The determination was made in a Dewar flask as calorimeter, fitted with thermometers and a regulator which controlled the temperature of the oil bath in which the flask was immersed. The regulator could be set so that as the temperature of the contents of the flask rose, that of the bath followed 0·5° C. or even less below. The heat production during oxidation of coal at 40° (soft coal) and 55° C. (hard coal) was found in each case to equal 2·1 calories per c.c. of oxygen absorbed. This is approximately half the heat produced when 1 c.c. combines with coal during complete combustion at high temperatures. With the aid of this value and on the assumption that it held good up to 120° C., it was possible to obtain an approximate value for the rate of heating of coal from the curves for rates of oxidation at different temperatures, assuming no heat loss and in the first instance no moisture present.

These results made it clear how spontaneous combustion occurred. A rapid absorption of oxygen at a normal temperature, *e.g.*, 30° C., would raise the temperature of the coal if the heat were not dissipated. The coal at the elevated temperature would absorb oxygen at an increased rate with further production of heat, the latter raising the coal to a still higher temperature, and so the cumulative effect would go on until the coal actually fired.

Approximate calculations have been made for the time taken for the various samples of coal experimented with to become heated spontaneously to 120° C. At this temperature there is no doubt that the further supply of oxygen would cause the material to fire in a short time. These calculations were based on a value of 0·3 for the specific heat of coal and on the assumption that the rate of oxidation of the dried material would be the same as that of the sample as tested, *i.e.*, with natural water content. Although subsequent experiments have shown these assumptions to be incorrect, the calculation figures may be of interest as giving an indication of the relative times taken by the various portions of the Barnsley seam to reach a temperature of 120° C. starting from 30° C.

A high rate of oxidation of the coal is not, however, the only factor governing the liability of a coal to spontaneous combustion. It is clear that a most important property is that of friability, since results of various investigators (especially Winmill) on the effect of size, and also the author's experiments on the impermeability of coal, show that the production of fine dust is a necessary factor. For example, the cannel coal experimented with showed quite a considerable oxidation, but it is extremely unlikely that this material by itself would be responsible for heating owing to its extremely strong texture. Barnsley softs, $35\frac{1}{2}$ hours; top softs, $37\frac{1}{4}$; Barnsley hards, $53\frac{1}{2}$; cannel, 77; "Jacks," 82; black shale, 422 hours to reach 50°.

An interesting experiment was carried out by Winmill on the rate of heating of Barnsley soft coal. The coal dust was dried *in vacuo* and oxygen admitted only just so fast as it was absorbed by the coal until the temperature reached 90° C., when a slow air current was maintained in order to sweep out the products of oxidation. The experimental results are given in Table II.

TABLE II.

During the heating of undried coal, however, a very considerable loss of heat occurs through evaporation of the contained water. The moisture content of the coal is, therefore, a very important factor. This point will be discussed later.

Influence of pyrites.

Many investigators (Plott, Parr and Kressman, and at one time J. S. Haldane) have believed pyrites to be the principal cause of trouble, whereas others, including Richter, Fayol, and Lowes, considered that it played a secondary part. It was generally thought that the two principal forms, cubical pyrite and orthorhombic marcasite, differed considerably in their ease of weathering—the latter being affected by oxygen and moisture much more rapidly than the former. That the pyrites theory was not necessary to explain all cases of spontaneous combustion was clear from the Doncaster Laboratory experiments on samples from the Barnsley seam. In other cases, however, the facts pointed to the pyrites being the principal contributory cause. For example, associated with some seams are bands of inferior material containing pyrites, and in many cases such seams are found to be particularly liable to heating.

Winmill measured the rate of absorption of oxygen by pyrites at 30°, and found that when finely ground *i.e.*, to pass a 60-mesh sieve, the material oxidised rapidly. Fineness of division was shown to be of much greater importance than in the case of coal.

Several different varieties of pyrites were tested by Winmill (Trans. Inst. Min. Eng., 1916, **51**. 500–509), who also examined the influence of fineness of division on rate of oxidation. Some of his results are given in Table III., in which is also given for comparison the rate of oxidation of Barnsley hard coal samples composed of particles of similar size.

Pyrites sample no. 1 was from a North Staffordshire seam and occurred mixed with carbonaceous matter to the extent of 81·3% FeS_2; the oxygen absorption is, however, calculated to 100% pyrites. Sample no. 2 was from the Barnsley seam, and was found in large crystalline masses which remained untarnished over long periods of time. Winmill's results show that the second sample, although in the coarse condition absorbing relatively little compared with the Staffordshire variety, when ground to pass a 200-mesh sieve absorbs oxygen at much the same rate as the Staffordshire variety passing 60-mesh. The rate of absorption of oxygen by coal sieved in a similar manner to no. 2 pyrites sample indicates clearly how the fineness of coal particles has a much smaller influence on rate of absorption. Winmill states that by washing the pyrites with dilute hydrochloric acid and thus removing the products of oxidation, the power of absorbing oxygen is very largely restored. The absorption of oxygen by coal cannot be renewed in this way, although Tideswell and Wheeler have found that by heating the sample after oxidation to a temperature of 200° C. *in vacuo* the oxidation complexes, or some of them, are decomposed, and the affinity of the material for oxygen at ordinary temperatures is renewed—a most important result which will be discussed later.

The reaction generally believed to take place during the oxidation of pyrites is given by the equation :—

$$2FeS_2+7O_2+2H_2O=2FeSO_4+2H_2SO_4$$

Ferric sulphate may also be formed, but not generally to any considerable extent until all pyrites has disappeared since ferric sulphate will be reduced by pyrites. Moisture is essential for the reaction. The author has confirmed Winmill's results, having found that even the most stable form of pyrites when powdered to pass a 200-mesh sieve absorbs oxygen rapidly. The heat produced during th oxidation of pyrites has been calculated by Parr and Kressman (Univ. of Illinois Bull., 1910, **8**, no. 16, 33) indirectly from Sommermeier's figures for the heat of combustion of ferric sulphide to ferric oxide and sulphur dioxide. The value obtained corresponds to 4·1 cals. per c.c. of oxygen absorbed during the atmospheric oxidation of pyrites. Winmill determined the value experimentally at 40° C. in the apparatus which was used for the similar determination of the heat produced during the oxidation of coal. He obtained a mean value of 4·5 calories with an error of 1·3 cals. He considers the value under mine conditions to be 4·3 cals. per c.c. of oxygen absorbed. This is just twice the heat production found during the absorption of a similar amount of oxygen by coal. These results are most important, as they indicate in a very clear manner when and how pyrites may be a dangerous factor in spontaneous combustion; when it is finely broken up or disseminated through carbonaceous material, rapid absorption of oxygen may occur with considerable evolution of heat, and consequent temperature rise. Since the rate of oxidation of pyrites has been found by Winmill to be doubled for a rise of 10° in temperature, this absorption of oxygen by pyrites will bring about a much more rapid rise of temperature than the oxidation of carbonaceous material alone. The facts that the rate of oxidation of pyrites at any given temperature does not fall off with time so rapidly as that of coal, and also that the oxidation may be increased by washing away the products (ferrous sulphate etc.), tend to render the presence of finely disseminated pyrites exceedingly dangerous. Reference has already been made to the belief that cases of spontaneous combustion in coal piles are more prevalent after showery weather. The author believes that a probable explanation of this is that oxidation of pyrites is accelerated through the removal of the products, and the warm solution of these draining to other parts helps to start the oxidation of fresh

material, probably pyritic in nature, at a higher temperature. It is obvious that even a small amount of pyrites, owing to its rapid oxidation, may raise the temperature of carbonaceous matter to a point at which it will absorb sufficient oxygen to carry on the combustion of the mass *per se*.

In the researches carried out in the Doncaster Laboratory and later in Birmingham, it was generally found more convenient to use coal samples crushed to pass a 60-mesh sieve, since the early experiments showed that the difference in rate of absorption of dust of this fineness and that passing 200-mesh was the same within experimental error. A vessel containing a known weight of coal dust mixed with glass wool was immersed in a thermostat, and a steady stream of fresh air from outside drawn by means of an aspirator through the mass of coal. The glass wool ensured that the air current did not follow definite channels in the dust, but percolated the mass of the coal. Samples of the issuing air stream were taken at intervals and analysed in the laboratory form of Haldane gas analysis apparatus, for carbon dioxide, combustible gas, oxygen, and nitrogen. At the higher temperatures of oxidation, tests for carbon monoxide were carried out in a modification of the Haldane apparatus designed for the purpose.* From the analyses of the samples and a measurement of the rate of flow of the aspirator, the rate of oxidation at any time could be calculated. As the rate of absorption of oxygen diminished, the rate of air flow was slowed down in order to obtain sufficient vitiation of the air to render the errors of analysis as small as possible. In carrying out oxidation in oxygen it has been found to be more convenient to use a more direct method in which the oxygen is pumped backwards and forwards from a reservoir to the reaction flask by means of a simple intermittent-pressure device worked by a water siphon, the gases being withdrawn at intervals from the reaction flask and reservoir, measured, and analysed.†

The author has recently used a third method for measuring rates of absorption and also total oxygen absorbed, in which a simple form of circulation apparatus is employed which can easily be fitted up in any laboratory. A full description of this is to be published shortly. Circulation is produced through the reaction vessel and a Winchester bottle by pumping the gases backwards and forwards with the aid of the above-mentioned system from a burette through small mercury valves arranged so that the current of gas always passes in the one direction. The burette and Winchester are immersed in a well-stirred water bath, or preferably a thermostat the temperature of which can be read to 0·02° C. The reaction vessel is immersed in a thermostat at the desired temperature and connexion made with capillary tubing. The total volume of apparatus is known, and volume readings may be taken at any time and also samples withdrawn for analysis. Very careful temperature and pressure readings are, of course, essential. Circulation at a rate up to 5000 c.c. per hour may be produced.

In 1915 Winmill (Trans. Inst. Min. Eng., 1915–16, **51**, 493) examined over 45 different samples of coal and associated material from different parts of the British Isles. In his results, which are for oxidation at 30° C., and in some cases 60°, he differentiates between the total absorption of oxygen and that used in the oxidation of pyrites, the amount of the latter being determined from the increase of sulphate content. Comparison of the various samples is made by the amount of oxygen absorbed in 96 hours. Those from the Barnsley seam showed absorption of from 300 to 500 c.c per 100 grams. Anthracite samples showed an absorption of 272 and 381 c.c. respectively at 30° C. At 60°, however, the anthracite appeared to absorb very little more than at 30°, thus differing very considerably from the Barnsley coal. South Wales steam coals gave figures varying from 79 c.c. to 134 c.c., whilst a temperature of 60° C. produced only a slight increase in the amount absorbed.

Northumberland and Durham coals with two exceptions gave absorptions of under 300 c.c. at 30° C., whilst at the higher temperature in the one case examined twice as much oxygen was absorbed. The Main seam and the Yard coal showed absorptions of 527 and 623 c.c. respectively, the latter taking up 1305 c.c. at 60° C. A certain amount of pyritic oxidation occurred with the former, whilst a sample of waste coal from this seam showed a total oxygen absorption of 511 c.c., pyrites being responsible for almost half of this. The higher rate of oxidation was however, not always found to be accompanied by prevalence of spontaneous combustion underground, since mining conditions may be such as to preclude the possibility of much small coal being left underground in the waste. On the other hand, the samples from the Main seam were from one of the few pits in which gob fires occur, although in normal working these appear to be rare. Samples taken from the Bullhurst seam showed absorptions varying from 81 c.c. to 167 c.c. at 30° C.; at 60° C., however, the absorption appeared to be nearly double—thus differing from the anthracites and South Wales coals. The cause of trouble in the Bullhurst seam appears undoubtedly to be due to pyritic oxidation; when this reaction has raised the temperature to a certain point, the oxidation of the coal will then produce sufficient heat for the combustion to continue. On the other hand the samples of coal from the Thick seam of South Staffordshire all showed absorptions of 300 to 530 c.c. Such absorption, especially the latter amount, classes the coal as dangerous. Of the samples from Ayrshire two showed high absorption—Bottom coal and Middle coal 502 c.c., Top coal (No. 3 seam) 392 c.c., whilst at 60° the first-mentioned sample absorbed 1100 c.c. The "smithy" coal which was suspected showed very little absorption (124 c.c.). The time/absorption curves were all of the same type, *i.e.*, showing rapid initial absorption which fell off quickly with time.

* Graham and Winmill, Chem. Soc., Trans., 1914, 105.

† Graham and Hill, Trans. Inst. Min. Eng., 1918, "Oxidisable Constituents of Coal, Part II."

Winmill summarises his conclusions as follows :—

(1.) Coals like anthracite and Welsh steam coals, which have a small definite capacity for oxygen, which is not altered by increase of temperature (at any rate up to 60° C.) and cannot therefore fire spontaneously.

(2.) Coals which have a low rate of oxidation, the capacity for which does increase with temperature, but are not liable to spontaneous combustion unless mixed with pyrites.

(3.) Coals which have a sufficiently large rate of oxidation to give rise to fires without the intervention of any other substance.

Those coals considered by Winmill not liable to fire usually absorb less than 200 c.c. of oxygen in 96 hours at 30° C., and those liable to fire well over 300 c.c.

The influence of moisture on rate of oxidation and on spontaneous heating.

An examination of the literature of the subject up to 1909 reveals a pronounced opinion in favour of the idea that moisture exerts a marked accelerating action on the liability of coals to fire both during shipment and more especially when dumped in large piles. Threlfall, referring to the English Commission of 1876, stated that an examination of the evidence showed this to be very largely a matter of impression only. In 1914 (Trans. Inst. Min. Eng., 1915, 49, 35) the author endeavoured to decide the matter by carrying out experiments upon the rate of oxidation of Barnsley hard coal.

Oxidation at 30° C.—(1) After heating at 100° *in vacuo*, the subsequent oxidation being carried out in dry air: Oxygen absorption found in 96 hours = 258 c.c. (2) Undried sample, subsequent oxidation in a current of air saturated with water at 30° C.: Oxygen absorption = 414 c.c. (3) Sample heated for 10 hours *in vacuo*; subsequent oxidation in air saturated with water at 30° C.: Oxygen absorption = 440 c.c. (4) Undried sample containing 7% of water in air from outside: Oxygen absorption = 435 c.c. (5) Sample dried *in vacuo* over sulphuric acid for 5 days, oxidation in dry air: Oxygen absorption in 96 hours = 265 c.c. (6) Sample dried *in vacuo* over sulphuric acid for 4 days, then heated 5 hours *in vacuo* at 100° C., oxidation in current of dry air: Oxygen absorbed in 96 hours = 270 c.c.

Oxidation at 50° C.—(7) Dried *in vacuo* over sulphuric acid (28 days), oxidation in dry air: Oxygen absorbed in 96 hours = 658 c.c. (8) Dried *in vacuo* over sulphuric acid (24 days), heated *in vacuo* at 100° C. for 20 hours, followed by oxidation in dry air: Oxygen absorption = 650 c.c. (9) Dried *in vacuo* over sulphuric acid (28 days), oxidation in current of air saturated with water at 50° C. Oxygen absorption in 96 hours = 945 c.c. (10) Undried sample containing 8% of water: Oxygen absorption = 850 c.c.

These results are taken from rate of oxidation curves and given in c.c. at N.T.P. per 100 g. of dry dust for 96 hours' oxidation.

The rates of oxidation of (2), (3), and (4) were almost identical, whilst (1), (5), and (6) had practically the same value, which is, however, approximately two-thirds of the rate with moist air. Similarly (7) and (8) were identical and about two-thirds of the value of (9).

These results were in agreement with those of Mahler, who found that coal when heated under pressure in the Mahler bomb absorbed more in the moist condition than when dry. The experiments of Richter (1870) gave contrary results (see later). Mention must be made here of the work of Katz and Porter (1917), who compared the oxidation of two coals at 25° C. (Illinois and Pittsburgh coals) over a prolonged period (100 days), in the dry and moist condition, the former condition being attained by desiccation over phosphoric oxide *in vacuo*, or in nitrogen, whilst the moist samples were air-dried. 100-gram samples (ground to pass 80-mesh but stopping on 100-mesh) were placed in flasks of 4½ litres capacity, which were immersed in a thermostat at 25° C., and connected to a manometer in which changes in pressure were noted at intervals. Dryness favoured the rate of oxidation of the Illinois coal, whilst the Pittsburgh coal oxidised slightly more slowly when dry than when moist.

The question of the difference in rate of oxidation of coal dry or moist is of more interest theoretically than practically, since coal in its natural condition, either underground or when stored in piles, will as a rule contain moisture in quantity to produce the maximum rate of absorption. The actual heating of coal will of course be retarded, since in the first place the greater the moisture content the higher will be the specific heat of the material and, what is more important, this moisture has to be completely evaporated before the material rises in temperature above 100° C.—a process requiring a considerable proportion of the heat produced even by a readily oxidisable coal (the evaporation of 10 grams of moisture from 100 grams of coal would require an amount of heat equivalent to that produced by the absorption of approximately 3 litres of oxygen).

These experiments were carried out not only for the purpose of ascertaining the influence of moisture but also to decide the question of the part played by bacteria in the reaction. The shape of the oxidation curves in the first instance and the fact that the persistence of this shape is evident at temperatures up to 160° C. are strongly against the view that bacterial action is responsible except to an exceedingly small extent. In a recent paper on the spontaneous combustion of hay (Fuel, Dec., 1923) J. S. Haldane has shown the typical shape of a curve obtained with oxidation which results from bacterial action.

In the author's experiments the fact that coal sterilised at 100° C. gave the same absorption (when oxidised under similar conditions in regard to moisture) as the unsterilised material clearly showed that bacterial action played no part in the oxidation of Barnsley coal. On the other hand Potter* concluded that slow oxidation of amorphous carbon and coal occurs at temperatures up to 40° C. through the agency of bacteria (*Diplococcus*). The insufficient precautions apparently taken to prevent oxidation of his samples during sterilisation will explain the

*Proc. Roy. Soc., 1908, B 80, 239.

absence of any appreciable amount of chemical oxidation taking place at low temperatures, although in his experiment at 100° C. one would have expected a measurable amount of carbon dioxide to be produced during the 20 days of his experiment. The quantities of carbon dioxide given off as a result of bacterial decay were exceedingly small,' and heat produced in such a way is negligible compared with that from the chemical oxidation of a coal freshly exposed to oxygen, even though the household coal used was somewhat coarse (viz., passing a sieve of 10 meshes to the inch and retained on one of 20).

From the practical point of view, it would thus appear that bacterial action may be safely excluded as a factor of any importance in the spontaneous nbustion of coal.

Adsorption of gases by carbon.

All coals, like charcoal, have adsorptive capacity for ies. This property has been studied in detail for ·ious gases under varying conditions of temperae and pressure, on moist and dry samples of coal. e amount of gas taken up is for the less readily ıorbed gases a linear function of the partial pressure.

t was not, of course, possible to determine the orption of oxygen directly, owing to the imposlity of differentiating between adsorption and nical oxidation. An indirect determination of the ›unt which would probably be taken up by fresh l was made by ascertaining the adsorptive capacity ›xidised dust for oxygen and nitrogen; and from ›mparison of these with the figure for the amount nitrogen taken up by the unoxidised material, igure of 65 c.c. adsorbed per 100 grams under tm. of oxygen at 30° C. is obtained. When the tial pressure is one-fifth of this (*i.e.*, for the amount ›xygen in ordinary air) it may be expected that quantity of oxygen adsorbed by coal will be about c.c. per 100 g. of dry dust. It was found that ist coal dust (*i.e.*, containing about 10% of isture) in general reduced the adsorbing capacity the dust to one-third of the value shown by the ›d material.

t will be seen that the actual volume of oxygen orbed by coal is small and that in the main the ›tion is a chemical one. At the same time it is lent that adsorption plays an effective part in reaction by bringing the oxygen molecules into mate contact with the readily oxidisable conuents. The heat produced by the adsorption of oxygen is very small—being, according to some experiments of the author's, about one-twentieth of that produced during the chemical oxidation. Partington's suggestion (1919) that adsorption alone is responsible has been shown not to be in accordance with experimental evidence (Wheeler, Chem. Soc. Trans., 1918).

References have already been made to the view that the moisture content (and especially that after air-drying) is a criterion as regards the liability of coals to spontaneous combustion. It seems clear that moisture (as found by an ordinary moisture determination at 105°) may be held by the coal in one or more of three different ways:

(1.) *Chemically-combined* owing to the existence in the coal of certain substances which combine with moisture to form compounds of the nature of hydrates. Some of these on heating to a temperature of about 100° C. appear to decompose with evolution of moisture.

(2) *Adsorbed moisture* retained on the free surfaces of the coal. With a considerable amount of adsorbed moisture the coal may still be quite dry to the touch.

(3) *Adherent or capillary moisture*—adventitious moisture—producing a feeling of dampness, or making the sample visibly wet.

It seems to be well established that part at any rate of the absorption is connected with the presence of substances which on heating evolve moisture—substances which are supposed by many (Dennstedt and Bünz etc., *loc. cit.*) to be of humic or ulmic (Schrader) nature and which give on oxidation hygroscopic acidic substances.

It seems probable that in the bituminous coals of high moisture content these substances may be present, whilst in coals such as South Wales steam they appear to be almost entirely absent.* Possibly the increased rate of oxidation of the moist sample may be connected with the oxidation of hydrated compounds, the formation of the hydrate, which is so readily decomposed by heat or desiccation, being necessary before such oxidation can take place. Adsorption alone cannot be responsible for high water content if the adsorption curve for gases can be compared with those for water—South Wales anthracite adsorbed slightly more gas than the Barnsley softs, whereas its moisture content after air-drying is about 1%, that of the Barnsley softs being about 5½% under laboratory conditions.

The author's experiments upon the products of oxidation at temperatures of 100° C. and below have shown that a considerable proportion of the oxygen absorbed reappears as moisture. During the first 5 hrs. at 50° C. 28·5%, and after about 100 hrs. nearly 40% of the oxygen which had disappeared has reappeared in the form of moisture. It is probable that the oxygen reappearing as moisture in this way first forms hydroxyl groups and that these are subsequently split off at a temperature of 110° (the coal being heated to this temperature for the determination of moisture). Earlier experiments

* It should be noted that in the author's experiments on the influence of water on the rate of oxidation, the moisture content of the original coal on air-drying was higher than that of the coals used by Katz and Porter, who obtained conflicting results.

had shown that the products of low-temperature oxidation consisted of small quantities of carbon dioxide and monoxide. The production of these expressed as a percentage of the oxygen absorbed increased with time at any one temperature, and also increased with temperature. Thus for Barnsley coal oxidised at 30° C., the amount of carbon dioxide produced expressed as percentage of the oxygen absorbed equalled :—

	30° C.	50° C.	70° C.	100° C.
At 4th hour	2·9	3	3·8	4
At 120th hour	4·2	7·7	12·5	20

The production of carbon monoxide in the initial stages of oxidation at 20° was 0·5% of the oxygen absorbed, rising to 0·7, whilst at 30° it was 1·0.

The average production of carbon monoxide expressed as percentage of oxygen absorbed over the first 100 hours of absorption has been found to be as follows :—

Temperature ° C.	CO produced as % of oxygen absorbed.
20	0·7
30	1·0
70	2·0
100	2·8
120	5·0
140	7·0

Oxidation of a sample of coal from the mid-seam Ayrshire showed (at 30° C.) a carbon monoxide production varying from 1·2% during the first 50 hrs. of oxidation to 2·0% after nearly two years' oxidation at about 20° C. and subsequent oxidation for 44 hours at 30° C. The carbon dioxide production after this prolonged oxidation was less than 20% of the oxygen absorbed.

With other coals, however, a smaller proportion of carbon monoxide has been found. Thus samples from the South Staffordshire thick coal (Brazill section) were found by the author to give carbon monoxide corresponding to 0·3% of the oxygen absorbed at 30° C. whilst similar results were found with fusain (Trans. Inst. Min. Eng., 1923, 66, [12] 41) and anthracite. Judging also from the vitiation of the air at the coal face in the Warwickshire thick coal seams, and the eight-foot coal in South Staffordshire, these coals appear to give considerably less carbon monoxide for a definite absorption of oxygen than does the Barnsley coal. Knowledge of the carbon monoxide and dioxide production relative to the oxygen absorbed is, of course, essential before deductions can be made from analyses of samples underground concerning the approximate temperature which coal or carbonaceous matter buried in the waste has reached.

Influence of composition.—(*a*) *As shown by ultimate analyses.*—Wheeler has shown that the temperature of ignition of coal dust is influenced by the oxygen content—the greater the latter the lower the temperature of ignition. Winmill's results also indicate, with one or two exceptions, that the greatest oxygen absorption and greater liability to spontaneous combustion is to be found with those coals containing a high percentage of oxygen. For example, the oxygen percentage of the Barnsley seam coals was between 11 and 13. The high percentage must not be taken by itself as the deciding factor, but, as both Wheeler and Winmill have pointed out (these investigators being thus in agreement with Dennstedt and Bünz), a high oxygen percentage probably indicates the presence of oxygenated compounds which are readily oxidi-able at ordinary temperatures. It seems probable also that these oxygenated compounds have the property of holding moisture as a loose chemical compound. From the experimental evidence available the author has no doubt that there are slight differences in constitution in the readily oxidisable constituents of various coals liable to spontaneous combustion and most probably in the proportion in which they are present.[1]

(*b*) *As shown by solvent action of pyridine.* Bedson, the pioneer as regards the use of this solvent for coals, believed that the extract, described as resinous, contained the substance responsible for the ready oxidation of certain coals. Lewes[1] and J. B. Porter[2] concurred in this view. Dennstedt and Bünz[3] examined the action of several solvents and concluded that the portion insoluble in pyridine was responsible for the main heating effect observed for the lignitious coals examined, as tested by their method, which involved heating in a current of oxygen at a high temperature. On the other hand Nübling and Wanner[4] found that the residue obtained by them had a higher ignition temperature than the original coals, whilst the extract had lower. Some careful experiments were carried out by J. Hill and the author[5] to ascertain the part played in low-temperature oxidation by the α and the $(\beta+\gamma)$ constituents, *i.e.*, the portions respecting insoluble and soluble in pyridine. Barnsley soft coal was extracted with pyridine in an atmosphere of nitrogen under reduced pressure and at a temperature of about 40° C. in order to avoid decomposition (*cf.* J. Harger, J., 1914, 389, and Illingworth, Trans. Sth. Wales Inst. Min. Eng., on the increased solvent action of pyridine at high temperatures).

The results (Trans. Inst. Min. Eng., 1917, 54, 197) showed clearly that the "α" compound—or insoluble portion—still contained the constituents responsible for spontaneous combustion. These experiments were confined to coal from the Barnsley seam; other coals of different type have been and are being investigated to determine whether the results obtained for Barnsley coal are in general true for all coals.

(*c*) *The macroscopic separation of coal.* The part played by the various ingredients of Stopes' classification has already been referred to. The four ingredients, durain, clarain, vitrain, and fusain, have been carefully examined by Tideswell and Wheeler, and by Lessing, by distillation and coking and as regards ash composition; from their results Tideswell and Wheeler advance the view that the first three differ in proportion of reactive and "inert" material, rather than in any distinctive types of

compounds. Oxidation tests support this view. The part played by fusain has recently formed the subject of a paper by the author (Trans. Inst. Min. Eng., 1924, 61, 41—57) and it would appear from the discussion, in which Drs. Wheeler and Tideswell took part, that this fourth ingredient of the Stopes classification may differ considerably as regards low-temperature oxidation. Such difference is perhaps more helpful than otherwise in the general elucidation of the problem, as it would appear to be bound up with difference in composition—Wheeler and Tideswell's sample showing a higher percentage of hydrogen possibly indicating the presence of a compound ontaining hydroxyl grouping). In general, however, t has been made clear that the average sample of usain (mother of coal or mineral charcoal) absorbs ery little oxygen in comparison with the other four ngredients, and that from the chemical point of iew this ingredient is not a primary cause of pontaneous combustion.

Space will not permit further discussion concerning he nature of the solid products of oxidation and he relation of these to the ulmins (*cf.* Boudouard, *oc. cit.*). Mention should be made, however, of the ork being carried out by Fischer and his co-workers t the Kaiser-Wilhelm Institut für Kohlenforschung, Iülheim-Ruhr, on the formation of coal. Their xperiments on high-pressure oxidation of coal, gnite, peat, etc., and the interesting observation f Schrader that the rate of oxidation of lignite and oal is considerably accelerated in the presence of lkali, render further investigation of ulmins most lesirable. There now appears to be a good deal of vidence showing that these substances play an mportant part, and similar investigations such as hose of Wheeler and Tideswell (Chem. Soc. Trans., 922, **121**, 2345) and others on these compounds and he constitution of coal will without doubt throw furher light on the chemical nature of the comounds undergoing spontaneous oxidation, and ender intelligible the experimental results already btained by the various investigators.

From the practical point of view, knowledge of he liability or otherwise of a coal to ignite sponaneously is obviously of great importance.

Schaper (Chem.-Ztg., 1919, 43, 401) indicates hat where the "ignition temperature" method is sed great care must be taken to commence the est at the same temperature if comparable results re to be obtained. This will be readily intelligible fter studying the figures (Table I.) showing rate of xidation of the various samples at different temeratures.

Actual measurement of the absorption of oxygen several temperatures (*e.g.*, 30°, 60°, and 100° C.), ugh, of course, taking considerably longer to carry , gives information of a more satisfactory charcter than the rapid test of "ignition temperature," ince the latter gives no indication of the behaviour f the coal at the lower temperatures—a behaviour hich is of the greatest importance in order to decide hether the coal can absorb oxygen at a rate sufficient o generate more heat than that which will be issipated by conduction or in other ways.

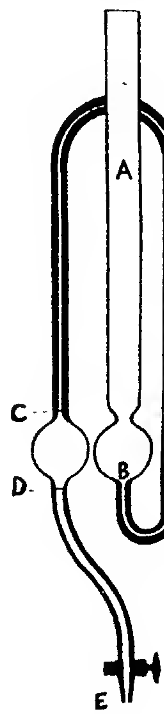
It must be remembered, however, that the physical properties of the coal, especially in relation to its behaviour during crushing, are just as important as the chemical property responsible for rapid rate of oxidation. The most readily oxidisable coal, if it is of strong texture capable of withstanding considerable pressure and grinding without the production of small coal and dust, will not readily fire.

A MERCURIAL VISCOSIMETER COMPENSATED FOR DENSITY.

BY F. M. LIDSTONE.

The viscosimeter to be described in this note is a modified form of one of which an account has already appeared (J., 1917, 270; 1918, 148 T).

Although not quite so simple in construction, it possesses two distinct advantages over the earlier type, viz.: (1) It is not necessary to know the density of the liquid as the head of the latter is nil. (2) The greatly increased length of the upper capillary, since it does not affect the head, enables accurate determinations to be made with thin liquids, such as water.



To use the viscosimeter the method of procedure is the same as before, viz., clean mercury is sucked up to just above B, and the stop-cock closed. A measured quantity of the liquid, very slightly in excess of the capacity of the bulb, is poured into A

and the temperature adjusted by means of the water jacket. The stop-cock is then opened and the stop-watch started when the mercury-oil meniscus passes C and stopped when it passes D. If the two bulbs are approximately of the same shape and size, the level of the liquid in AB will, as it falls, always keep approximately in line with the level of the mercury in CD, thus eliminating the head of liquid and leaving only the head of mercury. The time of efflux is thus, for all practical purposes, a function of the viscosity only, the correction for kinetic energy being very small, as also is the correction for the viscosity and kinetic energy of the mercury, provided the lower tube, DE, be moderately wide in bore.

These viscosimeters can be very accurately calibrated on the lines indicated in the paper by G. Barr (J., 1924, 29 T). There is obviously a slight modification owing to the absence of any head of liquid, and we thus get for the exact equation

$$\eta = K\left\{t - m - (n + rd)/t\right\}$$

where, using Barr's notation, $m = b\eta_m/S$; $n = qd_m/S$; $r = p/S$; S being equal to $a\eta_o/t_o + b\eta_m/t_o + qd_m/t_o^2$.

Although, strictly speaking, all the constants used in the calibration of these viscosimeters are only true for the particular temperature at which the instrument is calibrated, it will readily be seen that the variations in the constants, m, n, and r, due to temperature do not materially affect the final result and may, therefore, be neglected.

The change in the main instrumental constant, K, is, however, of just sufficient magnitude to make a small correction necessary This is due to the change in density of the mercury only; the changes due to the expansion of the glass cancel out, since the effect due to the increase in capacity of the bulb and the length of the capillary is exactly compensated by that due to the alteration in the radius of the capillary. All that is necessary to take into account is, therefore, the change in the effective head of mercury. The coefficient of expansion (absolute) for mercury being 0·00018, K must be multiplied by (1−0·00018T) if the temperature is T degrees above and by (1+0·00018T) if below the temperature of calibration. As an example, the following results are quoted to illustrate the degree of precision obtainable with one of these instruments. The apparatus was of the dimensions suitable for use with thin liquids such as water.

Dimensions.—Radius of upper capillary, 0·0248 cm.; length of upper capillary, 46·4 cm.; radius of lower tube, 0·125 cm.; length of lower tube, 9·83 cm.; mean head of mercury, 10·50 cm.; volume of bulb, 6·744 c.c.

Instrumental constants.—$a = 21{,}065 \times 10^5$; $b = 6{\cdot}9 \times 10^5$; $q = 0{\cdot}21 \times 10^5$; $p = 136{\cdot}4 \times 10^5$; $S = 1{\cdot}26 \times 10^5$; whence $m = 2{\cdot}3$; $n = 0{\cdot}09$; $r = 108{\cdot}3$.

Calibration at 20° C.

Liquid	Viscosity as determined by absolute viscosimeter.	Efflux time (in seconds).	K.
Water ..	0·01005	171·7	0·00005876
Typewriter oil ..	0·2973	5062	0·00005873

Owing to the lateral displacement of the lower part of the tube, DE, the alteration in the effective head of mercury caused by a deviation of the apparatus from the vertical or standard position becomes appreciable. It is most convenient to plumb the long straight tube, AB, and let the corresponding position of the tube, DE, be the standard one at which the apparatus is calibrated and used.

In conclusion, the author wishes to acknowledge his indebtedness to Dr. Guy Barr for numerous helpful suggestions and criticisms.

PLANT PIGMENTS.*

BY I. M. HEILBRON.

In the main, the pigments of nature may be divided into two classes, on the one hand the plastid pigments, chlorophyll and the carotinoids, which are common to all forms of land plants, and on the other the soluble sap pigments in which many well-defined groups are known, notably the yellow flavonols and the highly-coloured anthocyanins.

It is proposed in this paper to discuss briefly the general characteristics of these several groups and attempt, in so far as is possible, to follow their functions in the life process. As first in importance, the question of chlorophyll will be considered. The rôle played by this pigment is unique, and, without exaggeration, it may be claimed as the very essence of living matter, for the life and growth of plants are as dependent upon the presence of this substance as are human beings on the hæmoglobin of the blood. The pigment itself is contained within certain cells, the so-called chloroplasts, microscopic in dimensions but varying in size and form according to the species of plant. All chloroplasts so far examined appear to consist of two types of material—(*a*) A highly refractive colourless substance of proteinous nature which forms the basis of the chloroplast and bulks largely in its organisation; this substance appears to assume the form of an intricate sponge-work with innumerable and infinitely minute interstices. (*b*) An oily substance filling completely the interstices of the stroma and confined entirely within the limits of the plastid itself; in this oily substance the green pigment chlorophyll is contained in the form of an emulsion, and is apparently more concentrated towards the periphery of the plastid than elsewhere, even when fully developed. Its development and persistence appear to depend on the incidence of light upon the surface of the plastid, and, indeed, in the continued absence of light the chlorophyll disappears from the plastid altogether.

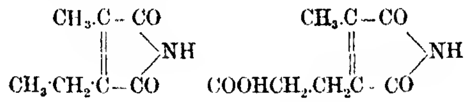
The story of its chemical investigation dates back to 1838, when Berzelius attempted to isolate the pigment from green leaves, but, being of the opinion that it was attacked neither by concentrated hydrochloric acid nor by alkalis, he treated the alcoholic extract of the leaves in such a violent manner that only decomposition products could actually have resulted. For many years following, other investigators attacked the problem in somewhat similar manner to that of Berzelius, without adding in any way much of importance. In 1879 Hoppe-Seyler attempted the isolation of chlorophyll, avoiding the use of chemical reagents, but his experiments produced negative results. Up till the year 1906 the main observations of value regarding chlorophyll are due not so much to chemists (although Schunck did much useful pioneer work) as to workers in other fields of science. On the one hand, the physicist, G. G. Stokes, in 1864 recognised from optical investigations the existence of two components in ordinary chlorophyll, and the Russian botanist, Borodin, observed in 1881 the formation of the so-called crystalline chlorophyll by the drying of leaf sections moistened with alcohol. This discovery, which is actually of enormous import, remained valueless until it was repeated for a second time in Willstätter's laboratory. When this latter investigator, to whom most of our knowledge regarding the constitution of the pigment is due, started his researches, chlorophyll in its solid state was unknown, as also any method of obtaining sufficiently pure solutions for a chemical investigation. Willstätter applied himself in the first place not directly to the examination of the pigment itself but rather to a study of its constitution through the derivatives obtained from it on treatment with acid and alkali. Chlorophyll itself is neither a base nor an acid, but when treated with alkali in alcoholic solution, it is converted into products—the so-called phyllins—which are acid in character, yielding soluble alkali salts. In this reaction, in addition to hydrolysis, a primary change occurs which can be directly observed owing to the alteration in colour which takes place, the green chlorophyll solution changing to brown and then back again to green. This phase phenomenon is termed "allomerisation," and occurs in alcoholic and other solutions, also extremely readily in presence of traces of alkali hydroxides. According to Willstätter, the reactions which occur are due to a rearrangement of a lactam group in one of two ways depending upon whether hydrolysis is brought about in cold or in hot solution. It has been ascertained that the first stage in the hydrolysis is the removal of an alcohol having the formula $C_{20}H_{39}OH$. This substance, known as phytol, is obtained as a colourless, thick oil and has the properties of an unsaturated primary alcohol containing a branched open chain of carbon atoms. It is probably closely connected with isoprene, which may also be looked upon as the progenitor of the terpenes and caoutchouc. In the leaf itself there is present an ester-splitting enzyme—chlorophyllase—which has the power of replacing the phytyl residue by the ethyl radical when allowed to act in alcoholic solution, and the ethyl chlorophyllide thus formed is identical with Borodin's crystalline chlorophyll. On the other hand, the enzyme acts in aqueous acetone solution producing a monocarboxylic acid, chlorophyllide, which still contains, however, a carbo-methoxy ester group which is hydrolysed by alcoholic potash to give dibasic acids—the so-called chlorophyllins. The reaction with alkali in the cold and in the heat leads to the production of different chlorophyllins, of which four

* Read at a joint meeting of the Liverpool and Manchester Sections on Feb. 22, 1924.

were definitely isolated. In these four substances it was found that magnesium was present, the metal being present as a co-ordinated complex not dissociated in solution. By treatment of the chlorophyllins with alcoholic potash under pressure, monocarboxylic acids are formed, and finally, on treatment of these with soda-lime, an oxygen-free compound, the so-called ætiophyllin, having the formula $C_{31}H_{34}N_4Mg$, results. With either the pigment itself or any of its derivatives, in every case treatment with acids brings about an immediate alteration in colour of the solution from green to olive-brown, which colour change is coincident with the removal of the magnesium atom and its replacement by two hydrogen atoms without otherwise altering the composition of the molecule. Thus from chlorophyll there results, on treatment with alcoholic oxalic acid, the magnesium-free compound known as phæophytin. In this compound the magnesium atom is quantitatively removed and replaced by two hydrogen atoms. Both ester groups, however, remain intact. Phæophytin is fairly readily obtained in a pure state free from fat, waxes, and other colourless or coloured impurities. On treatment with boiling methyl-alcoholic potash, it is hydrolysed just as chlorophyll itself is, and yields two extremely important products—a lactam dicarboxylic acid, phytochlorin "e" $(C_{31}H_{32}N_4)(CO)(CO_2H)_2$, and phytorhodin "g," which is obtained in dark reddish-black crystals and has the formula $(C_{30}H_{31}N_4)(CO)(COOH)_3$.

The production of these two acids so similar in constitution to each other and having approximately the same molecular weight as phæophytin, the inability of converting one into another, and the fact that they are invariably obtained in definite amounts, led Willstätter to conclude that phæophytin, and consequently chlorophyll, is actually a mixture of two components, phytochlorin "e" being a product of one and phytorhodin "g" a product of the other. This conclusion is in strict agreement with Stokes' observation and also harmonises with adsorption experiments carried out by the botanist, Tswett, in Warsaw. The complete experimental justification of these views was finally given in 1911 when the isolation of chlorophyll itself was achieved and its separation into its two components—chlorophyll "a" and chlorophyll "b"—accomplished. Chlorophyll "a" is obtained as a blue-black powder which dissolves in alcohol with a blue-green colour and deep red fluorescence. Chlorophyll "b" is a dark-green powder less soluble in light petroleum than the "a" component. In the phase changes, chlorophyll "a" passes into yellow, chlorophyll "b" into red, the original colours being obtained again more quickly with the "b" than with the "a" component. Analysis of the two compounds gives the following:—For chlorophyll "a": $C_{55}H_{72}O_5N_4Mg,\frac{1}{2}H_2O$. For chlorophyll "b": $C_{55}H_{70}O_6N_4Mg$.

The exact constitution of the pigment has not as yet been completely elucidated. According to Willstätter, ætioporphyrin, the magnesium-free crystalline base obtained from both chlorophyll "a" and "b" has the composition $C_{31}H_{36}N_4$. This substance has also been obtained from hæmoglobin and thus once again a direct continuity is revealed in living matter. The oxidation of chlorophyll derivatives leads to the imide of methylethylmaleic acid (I.) and hæmatinic acid (II.).



I. II.

By the reduction of chlorophyll hæmopyrrole is formed, a complicated mixture of pyrrole homologues.

The so-called carotinoids are red, orange or yellow pigments which can be extracted from tissues by fat solvents and are found abundantly in all forms of living matter both in the plant and animal kingdoms. Nothing definite regarding their structure is known. The first yellow plant pigment of this group to be isolated in crystalline form was carotin, the pigment of the root of the cultivated carrot. This chromolipoid is a hydrocarbon and all such substances whose constitution and properties are similar are designated carotins. On the other hand, there occur various oxyhydrocarbons which appear to be generically related to carotin. These are termed, according to Tswett's terminology, xanthophylls. Carotin itself was first described in 1826 by Wachenroder, who obtained it by ether extraction of dried macerated carrot roots and in this way isolated the pigment in ruby-red quadratic crystals. Various formulæ have been ascribed to this substance, but its composition was only definitely settled by Willstätter and Mieg in 1907, who showed it to be identical with the carotin which invariably accompanies chlorophyll "a" and "b" in the chloroplastid of the green leaf. The molecular formula of the substance is $C_{40}H_{56}$. The appearance of carotin together with chlorophyll was first noted by Stokes, but it was left to Willstätter to point out, by the study of innumerable species of land plants, its invariable existence in all green leaves. Stokes also mentions the existence of another yellow pigment now known as xanthophyll, and this has also been isolated in crystalline form by Willstätter and shown to have the molecular formula $C_{40}H_{56}O_2$. As regards the xanthophyll series, Tswett, by a study of the adsorption coefficients towards finely divided materials such as calcium carbonate, has been able to prove that the xanthophyll which accompanies carotin in the green leaf is a mixture of at least three and possibly four isomeric substances, designated as xanthophyll a, xanthophyll a′, xanthophyll a″, and xanthophyll b, the last named showing the greatest adsorption affinity for calcium carbonate and consequently existing in the largest colloidal aggregates. According to this investigator, crystalline xanthophyll is a mixture of two or three isomeric xanthophylls in which xanthophyll "a" predominates. These pigments are not alone common to green plants, but the vast majority of yellow to orange-red flowers and fruits owe their colour, at least in part, to chromoplastids containing carotin-

oids. Thus, the red tomato is characterised by the red carotinoid lycopin, which is isomeric with carotin, and crystallises in carmine-coloured aggregates. In the algæ, especially the brown sea-weeds, a carotinoid known as fucoxanthino has been definitely characterised. This carotinoid crystallises from concentrated ethyl alcohol in long amber-coloured prisms, and has the empirical formula $C_{40}H_{56}O_6$.

It will be seen from the foregoing that the carotinoid pigments are extraordinarily widely diffused in the vegetable kingdom, and consequently it is not surprising to find them equally widely distributed throughout the animal kingdom both among the vertebrates and invertebrates. The existence of a chromolipoid in the blood serum of certain mammals was known as early as 1835, but the relation of this pigment to the carotinoids was not established until the work of Palmer and Eckles in 1914. The chromolipoid of cattle and horse serum is carotin, but in man it may be either carotin or xanthophyll. The chromolipoid pigments of birds are of interest. The egg-yolk pigment was studied as early as 1867, and although its chemical relation to plant xanthophyll was suggested by Schunck in 1903, this was first definitely established by Willstätter and Esher in 1912. The yellow to red colours of feathers are also unquestionably due to carotinoid pigments, xanthophyll probably being most commonly present. Among the invertebrates, carotinoids are also abundantly present.

Recent investigations tend to show that all animal chromolipoids are derived from the carotinoids of the food, and, either unchanged or slightly modified, are the cause of the yellow to red colours of all species of animal. Their significance in the living organism has not been definitely fixed, but I shall endeavour to show immediately a probable function of carotinoids in plants. In animals our knowledge is not as yet far enough advanced to indicate any general physiological function, but the mere fact that they vary in amounts in animals fed on the same foods would seem to indicate that they play a definite rôle. It was at one time considered that a direct connexion existed between carotin and vitamin A, but this has not been substantiated by recent work of Coward and Drummond, whose experiments have proved that although the synthesis of this vitamin is undoubtedly associated with the formation of chlorophyll in the leaf, no correlation with the carotinoids can be detected.

Function of chlorophyll in plant assimilation.

As is well known, the term "photosynthesis" is applied to the process whereby the green plant in presence of sunlight and water is able to bring about the assimilation of carbon dioxide into sugars and other complex organic compounds. The photosynthetic process is still largely wrapt in mystery, but it is to-day generally recognised that chlorophyll is the active medium concerned in the operation. As to the function of this pigment in the assimilation process, Willstätter has definitely proved that formaldehyde must undoubtedly be the initial organic compound formed. According to this investigator, the process takes place in such a way, that under the influence of light, a chlorophyll-carbonic acid complex passes into a chlorophyll-formaldehyde peroxide, which in turn is deoxidised by means of an enzyme with liberation of formaldehyde and evolution of molecular oxygen. With experiments carried out *in vitro* it has been shown that actually, provided sufficient energy is given to the system, formaldehyde can be detected in a carbonic acid solution.[1] The minimum amount of energy required to activate the molecule of carbonic acid in this way is of the order of 150,000 calories. Moreover, when formaldehyde solutions are exposed to short-wave light, the formaldehyde molecules take up energy and are converted into "active" formaldehyde, and in this condition immediately undergo condensation to reducing sugars. From a consideration of the energy required to proceed from carbon dioxide to hexose sugars, it seems in the highest degree improbable that the energy which the chlorophyll complex alone is able to absorb would be sufficient to bring about the complete reaction. On the other hand, if the reaction takes place in stages in which both chlorophyll components, as well as the two carotinoid pigments, are involved, from theoretical considerations there would then be no difficulty in obtaining the necessary amount of energy. That the four pigments are actually employed would seem extremely probable when one considers that, to convert a molecule of chlorophyll "a" into chlorophyll "b" two atoms of oxygen are required, which is in exact agreement with the quantity of oxygen evolved during the transformation of a molecule of carbonic acid into formaldehyde and, finally, agrees absolutely with the oxygen ratio existing between carotin and xanthophyll. In support of this hypothesis, which at any rate it must be admitted is highly plausible, some very interesting experimental confirmation has recently been obtained.[2] By a close study of pure carotin solutions, very definite spectrographic evidence has been obtained that, under certain conditions, carotin does actually pass into xanthophyll. According to these views, each pigment definitely functions according to the following scheme.—

Chlorophyll "a," carbonic acid $\xrightarrow{\text{light}}$ chlorophyll "b"—hydrate + formaldehyde

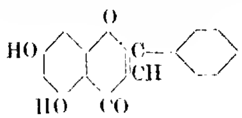
Chlorophyll "b" + carotin = chlorophyll "a" + xanthophyll.

Whether or no the xanthophyll in turn is deoxidised back to carotin by enzyme action, or whether purely chemical reduction occurs is at present being investigated, as also the problem regarding the transformation of the chlorophyll "a" into the "b" component.

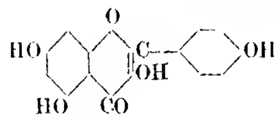
The pigments hitherto considered are all intimately connected with organised protoplasmic substance, and we may now turn to the consideration of colouring matters which exist in a state of solution in the cell sap. Such pigments are characterised generally by the presence of hydroxyl groups in the molecule, that is, they are for the most part phenolic compounds, the constitution of which has in the main been elucidated. Thus we find that several very important

[1] Baly, Heilbron, and Barker, Chem. Soc. Trans., 1921, 119, 105.
[2] Unpublished work in the Department of Inorganic Chemistry, Liverpool University.

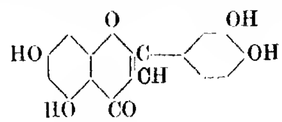
groups may all be regarded as derivatives of unsaturated hydroxyketones containing the linking Ph.C.C.C.Ph. The three important families under this heading are the flavones, flavonols, and anthocyanins. In the flavone group the parent substance is itself met with in nature as the characteristic dust present in many varieties of the primula. Other members of this family which may be mentioned are chrysin (I.), contained in the leaf buds of the poplar, apigenin (II.), met with in the form of its glucoside apiin in the leaf, stem and seeds of parsley, and luteolin (III.), the main colouring matter of weld, the oldest European dyestuff known :—



I.

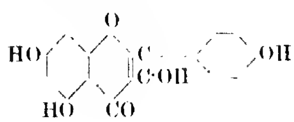


II.

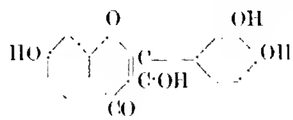


III.

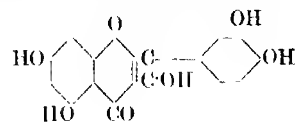
As examples of the widely distributed flavonol group, kaempferol (IV.) found in *Delphinium consolida* a member of the larkspur family, fisetin (V.) the colouring matter of young fustic, quercetin (VI.), the important yellow dyestuff extracted from quercitron bark, which is the inner bark of a species of oak native to the southern States of America, and in which the pigment is present in the form of a glucoside associated with rhamnose, and myricetin (VII.), the colouring matter of an evergreen tree met with in the tropics, may be quoted :-



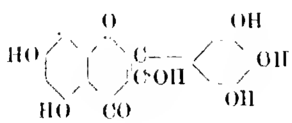
IV.



V.



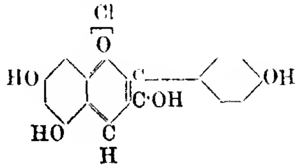
VI.



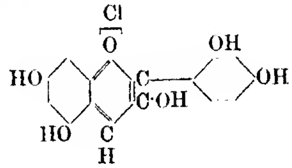
VII.

Closely associated with the flavones and flavonols there still exists a further group of pigments which are by far and away the most fascinating of the series. These are known as the anthocyanins, and it is to their presence in flowers that the red, blue and purple hues which nature so lavishly supplies, are due. Chemically, the anthocyanins are extraordinarily interesting, for although they are nitrogen-free and contain hydroxyl groups, at the same time they react as bases. It is remarkable how nature shuns the employment of nitrogen in her colour schemes, and probably views with indulgent disdain our feverish efforts to multiply azo, sulphur, and other complicated synthetic dyes from coal tar.

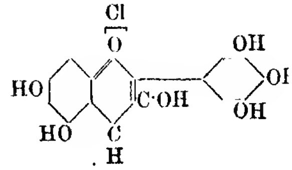
The term anthocyanin seems to have been coined by Marquart in 1835, although flower pigments had actually been investigated at a much earlier date. Thus directions concerning the extraction of the colour pigments of blossoms are found in the writings of Robert Boyle so early as 1664. Prior, however, to 1913, when Willstätter commenced his investigations on these substances, nothing very definite concerning their constitution was known. Willstätter and his collaborators were able to show that the diverse colours of flowers, whether the brilliant red deep violet or blue, were occasioned by quite minute changes of basal material. As present in nature, the anthocyanins are glucosides, yielding on hydrolysis a simple sugar—dextrose, galactose, or rhamnose—and the chromogen to which the distinguishing name anthocyanidin was applied. As regards the chemica constitution of these pigments, this was fairly readil arrived at, for on treatment with alkali all antl cyanidins break down to yield phloroglucinol a hydroxybenzoic acids such as *p*-hydroxybenzoic ac protocatechuic acid, and gallic acid, or their metl ethers. As similar products are obtainable from t flavonols, strong evidence is afforded of a structu connexion between the two groups, and the ant cyanidins are now recognised as oxonium salts ba on the following three formulæ :—



VIII.



IX.



X.

It will thus be observed that the anthocyanidins are actually reduction products of the flavonols, and the successful reduction of quercitin to cyanidin has been accomplished independently by both Everest and Willstätter. The three compounds, pelargonidin (VIII.), cyanidin (IX.), and delphinidin (X.), form the bases of all flower pigments, so far, at any rate, as has as yet been observed.

The different types which occur in nature are due either to the presence of different glucosides, on the one hand, or to methylation of the free hydroxyl groups on the other hand. As an example of this, cyanidin is met with as a monoglucoside in asterin, the pigment of the purple-red aster, and as chrysanthenin, which is isomeric, the pigment of the deep red chrysanthemum. On the other hand, idaein, the colouring matter of the cranberry is a galactoside of cyanidin. Cyanin, which is the pigment of the rose, dahlia, peony or cornflower, is a diglucoside, and isomeric with mekocyanin, the pigment of the purple-scarlet poppy. Again, keracyanin, isolated from the cherry, is a diglucoside containing both dextrose and rhamnose. According to Willstätter, the red coloration is due to oxonium salt formation, whereas the blue colour of flowers is to be ascribed to the formation of potassium salts of the oxonium base. The free base itself is purple in colour, but rapidly passes into the colourless carbinol. With these views, I myself am not wholly in agreement, for in the preparation of somewhat similarly constituted compounds in these laboratories, we have found that colour change from red to blue is only reached when a free hydroxyl group is present in the 4′-position of the 2-phenyl group, and according to our views, the change from red to blue is due to change of structure from the oxonium to a pyrone-quinonoid type.

The wonderful alterations in leaf colour observed in flowers are due to a variety of causes, notably the presence of different anthocyanins in the same plant or even in the same leaf. Colour variation depends also on the quantity of pigment present, as also on the acid or alkaline character of the cell juices. Frequently, moreover, flavonols, carotin, or xanthophyll are also associated with the anthocyanin pigment, producing in this way a variety of hues of unsurpassed beauty.

Although the constitution of the anthocyanin pigments has been conclusively proved by their direct synthesis in the laboratory and their relation to the flavonols equally definitely arrived at, the method by means of which they are synthesised within the living cell is still obscure. Fairly conclusive evidence seems to show that anthocyanin production is not directly photosynthetic, but that, indeed, the appearance of the pigment accompanies lessened photosynthetic activity such as is found in plants towards the end of their vegetative season. The same obscurity is met with when the physiological significance of the anthocyanins is considered. Here again, in contradistinction to the chlorophyll pigments, no satisfactory explanation has been arrived at. It has been suggested that they act as light screens shielding the chloroplastids from too intense insolation. Again, it has been advocated that their function is to bring about absorption of light rays and their conversion into heat, thus raising the temperature of the plant tissues. Against both these views many objections can be raised, and much further research is yet required to account satisfactorily for the formation of these wonderful and fascinating pigments. There can, however, be little doubt that they do actually play a very definite rôle in the life-mechanism of the plant.

In conclusion, the author desires to make grateful acknowledgement to the authors of the following books for the free use which has been made of their contents: R. Willstätter and A. Stoll, "Untersuchungen über Chlorophyll," A. G. Perkin and A. E. Everest, "The Natural Organic Colouring Matters," Leroy S. Palmer, "Carotinoids and Related Pigments."

THE ANALYSIS OF LYSOL.

BY A. H. DODD, B.A., A.I.C.

The *Liquor cresolis saponatus* of the Pharmacopœia is required to contain 50% of cresols. Most Lysols on the market also claim to contain this quantity, but there are brands of lower strength. There appears to be no really accurate method for a rapid determination of the percentage of cresylic acid in these products (*cf.* Schmatolla, Chem.-Ztg., 1922, 46, 661).

In the examination of Lysols and similar compounds, the mixed tar, fatty, and rosin acids are separated from the oils, after demulsification, by extraction with sodium hydroxide solution and subsequent liberation with acids and extraction with ether or benzol.

This paper deals with the separation and measurement of the tar acids. In practice it is not usually required to know the composition of the tar acids; all that is necessary is that they should distil between the usual limits.

Separation of phenols from fatty acids etc.

Generally the cresols or tar acids are separated from the fatty or rosin acids by distillation with steam or by simple fractional distillation, it being assumed that the fatty or rosin acids are much less volatile.

There are special methods which can have only a limited application, *e.g.*, that of separating the barium or calcium salts of the soaps, which only succeeds with certain fatty acids such as oleic acid. Weyl's method of forming a soap in ethereal suspension with sodium carbonate (Ber., 1889, 139) seems never to have been developed, probably because emulsions are formed from which it is difficult to separate the cresols.

Separation of phenols by steam distillation.

In the "official method" of the German Pharmacopœia (Vol. 5) the acidified Lysol is distilled with

steam until the distillate is no longer turbid. The cooling water of the condenser is then turned off until steam issues from the condenser, after which steam distillation is continued for five minutes longer with cooling. The distillate is assumed to contain all the phenols. The U.S Dept. of Agriculture has issued a pamphlet* in which steam distillation is recommended to remove tar acids from the U.S.P. *Liquor cresolis compositus*.

Despite its obvious convenience, there is one serious objection to the method. The cresylic acids of commerce which are invariably used in Lysols contain varying percentages of higher-boiling phenols. These are present in the "water white 97–99% commercially pure cresylic acid." They are extremely difficult to volatilise in steam, especially in the presence of fatty acids, which lower the vapour pressure of the tar acids very considerably. Thus in one experiment 1 gram of pure xylenol was completely removed from a water suspension by 300 g. of steam; when excess of fatty acids and rosin were present 1200 g. of steam were required before the distillate gave a negative test for phenols. Edwards and Freak (J., 1920, 326 T) state that tar acids of b.p. above 250° (small quantities of which exist in ordinary cresylic acid) are not volatile in steam.

Hence, even if it be possible to distil the whole of the tar acids with steam, large volumes of distillate will be obtained. This is a great disadvantage when it is desired to extract the tar acids with ether or to concentrate with sodium hydroxide solution before acidification.

Jordan and Southerden (Pharm. J., 1921, 479) have suggested a very simple method for the examination of Lysol, in which it is distilled with steam until the distillate gives no coloration with ferric chloride. The distillate is allowed to settle and the volumes of oil and water are measured. It is assumed that the cresols are soluble to the extent of 1 part to 50 of water. Apart from the defect mentioned above, the assumption as to solubility is hardly warranted, since the solubilities of the *o*- and *p*-cresols are 2·5 and 1·8 parts per 100 respectively. In one instance using this method the aqueous distillate obtained was more than sufficient to dissolve all the cresol.

Martin (Analyst, 1921, **46**, 451) points out that certain fatty acids, being volatile in steam, may vitiate the method. With such fatty acids as the author has tried (oleic acid, and those of cotton seed, palm, and linseed oils) the error is negligible. Fischer (Arb. K. Gesundheitsamt, 1903, **19**, 577) made a detailed study of the separation of fatty acids from phenols by steam distillation, and came to the conclusion that with ordinary fatty acids met with in commerce the error was not appreciable.

Jordan and Southerden's method has the further disadvantage that the phenols will not separate in a definite layer, thus rendering the reading somewhat uncertain. The method is, however, useful for control purposes in works using a known cresylic acid.

* "The Analysis of Coal Tar Creosote and Cresylic Sheep Dips," Chapin, 1908.

The methods usually employed for determining the amount of tar acids in the steam distillate are as follows:—

(1) Extraction of the phenols by means of ether and subsequent drying at 100° C.†
(2) Formation and concentration of the phenates and subsequent acidification and measurement of volume of phenols.
(3) Noting the change of volume of caustic soda when the phenols are dissolved in it.

In the first method the water is not driven off from the cresols at 100°C., and at higher temperatures there is the possibility of loss of phenols. Schmatolla (*loc. cit.*) states that cresol holds back ether even on evaporation at 150°.

The process of concentrating the phenate solution and acidification has the merit of simplicity and is recommended by Schmatolla. Chapin points out, however, that the higher phenolates are hydrolysed by repeated boiling with water, and there is a danger of "cracking" under this somewhat drastic treatment, "pitching" undoubtedly taking place.

Chapin's method (*loc. cit.*) consists of extracting the tar acids with benzol, producing the phenate by adding 1 : 2 caustic soda to the benzol solution, evaporating off the bulk of the benzol, decomposing the phenates with acid, and extracting the phenols with benzol. Method 3 above is used for measuring the volume of tar acids (*cf.* Spalteholz, Chem.-Ztg., **22**, 58). The benzol extract is added to 1 : 3 caustic soda, and it is assumed that the volume increase in the soda is 1 c.c. for every gram of cresol.

Chapin gives (*loc. cit.*, p. 32) an analysis of a Lysol by this method in which the error is 0·02%, but with other samples containing 50% of cresylic acids the results varied between 38 and 45%, the average being 42%.

One undesirable feature of the process is that in order to get a sufficiently large volume increase of the soda, a large quantity of Lysol must be used. Also the separation of the tar acids from the acid must be absolute, since a reading error of 0·05 c.c. represents 1% on 5 g. of lysol. Further, 1 g. of cresols does not necessarily give an increase of 1 c.c. (Edwards and Freak, *loc. cit.*); the author has found that 1 g. of Kahlbaum's xylenol (b.p. 211° C.) gave an increase of 0·88 c.c. only (xylenol is found in cresylic acids of commerce from low-temperature tars).

Distillation method of separating tar acids from fatty acids etc.

This method is not generally recommended, since it is known to be impossible to separate accurately two oils of different boiling points by mere distillation. For example, the Swiss authority demands that *Liquor cresolis saponatus* should contain 50% of phenols and cresols boiling between 187° and 210°, and on distillation of 100 c.c. and salting out, 45 c.c. of cresols should separate.‡ This method is evidently

† Frank (Chem.-Ztg., 1922, **46**, 390) proposes to extract the untreated lysol with ether, evaporate the extract, and dry this for one hour at 100° C., the product being considered as tar acids. This method, however, would only be suitable for solutions of pure cresols in absolutely neutral soap made from strong fatty acids.

‡ Most Lysols contain 20-30 parts of fatty acid to 50 of cresylic acid

inapplicable when a considerable proportion of the cresylic acids consists of high-boiling constituents, but as such divergent results were obtained by other methods, it was resolved to test it, since its simplicity is one advantage over the methods described.

A dozen samples of the fatty acids used in commercial Lysols were examined and found to have distilling points well above 300° C. On distilling commercial water-white 97–99% cresylic acids, 95% distils below 210° C.; hence it should be possible to achieve a fairly sharp separation of mixtures of fatty acids and ordinary cresylic acid by fractionation. The ordinary counterbalancing effects of the lower-boiling constituent of the mixture carrying over with it a certain proportion of the higher-boiling constituent and *vice versa* can be allowed for. A study of mixtures of various fatty acids and cresols showed that under specified conditions, and in view of the fact that commercial Lysols are very uniform in composition, it is possible to apply a correction which gives satisfactory results.

There is a choice between two methods of procedure. The tar acids may be separated by fractionation, or a correction may be applied according to the nature and quantity of the fatty acid, which is found by weighing the residue after the tar acids have been removed.

The process decided upon after lengthy trials was as follows: the Lysol is measured into a suitable separating funnel—at least 100 g. should be taken—and shaken with a sufficient volume of 2% sulphuric acid to destroy the emulsion and decompose the fatty acids. About 50 c.c. of ether are added, and, after standing, the supernatant oil is separated. In most instances the dilute acid is again washed with 20 c.c. of ether, and the ether added to the ethereal solution of fatty acids and phenols, which is then allowed to dry over fused sodium sulphate. This is essential in order to get a sharp separation in distilling. The oils are then filtered through a folded paper into an ordinary 250-c.c. distilling flask with side arm, and washed in with more ether. During distillation the flask and gas burner are completely enclosed in a metal cylinder, and the thermometer projects from a sheet of asbestos used as a cover. The thermometer bulb should be at least 2 cm. below the exit of the arm.

Many attempts were made to modify this procedure to obtain more accurate results. For example, test mixtures were distilled in fractionating columns, but it was found that the amount of liquid left in the column detracted from the advantage of the fractionation. Distillation with successive portions of paraffin (generally used in America in distilling tar acids) presented no advantage, as the traces of fatty acid distilling over formed a soapy meniscus when the cresols were dissolved in soda.

After distilling off the ether on a water bath, the fraction which passes over from 100° to 160° C. is collected in a small measuring cylinder, and tested for ether by shaking with a few c.c. of strong caustic soda solution and measuring the volume of ether on the surface, or alternatively by dissolving the tar acids in 5 c.c. of 1 : 3 caustic soda solution and measuring the increase in volume.

The phenols are then allowed to distil over slowly at the rate of 1 to 2 drops per sec. If the flame is kept constant it will be found that the temperature will gradually rise to a maximum—somewhere about 215° C. according to the cresylic acid employed—but the rate of distillation will fall. The temperature will then drop. All the time, however, phenols will distil very slowly owing to a fractionation taking place. The flame is gently raised so that temperature rises about 5° above that reached before. After more drops have come over the thermometer again falls. It has been found that on the third time of heating the temperature can be raised to 230° C., impure cresylic acid coming over. After this an increase in the size of the flame sends the thermometer rapidly up to 300° C.

Although it is advisable to use 100 g. of the Lysol for each test, this is not always possible. In a sample of Lysol of unknown cresylic acid content examined by the author, 18·4 and 17·9% were found working with 50 g. each time. Actually 18·2% was present.

In order to determine the corrections necessary, curves were drawn up. As an alternative to these the following table gives the percentages of cresylic acid distilling at the various temperatures when mixtures of the usual quantities of oleic acid and cresylic acid were distilled. The first series (to 225°) shows the temperature and amount obtained on the first heating, and the second (to 220°) the amount obtained after allowing the temperature to fall and raising the flame. In the third series the mixture was slowly distilled to 230°. The amount of cresylic acid which can be obtained by distilling the usual mixture of fatty acid and cresylic acid appears to be about 98.5%:—

		% of cresylic acid distilled of that actually present			
	Mixture	1	2	3	4
	Oleic acid	80 g	70 g	65 g	60 g
Temperature.	Cresylic acid	20 g	30 g	35 g	40 g
°C		%	%	%	%
205		82.0	76.0	75.0	62.0
210		89.5	87.7	87.0	86.0
215		90.6	90.8	89.[illegible]	89.0
220		92.7	92.75	92.7	90.1
225		—		96.2(*a*)	94.3(*b*)
190		94.2	94.5	98.2	95·5
200		94.5	94.8	98.2	95.75
205		94.6	95.2	98.3	96.5
210		95.9	96.0	98.1	96·5
215		96.0	96.2	98.1	96·6
220		97.1	96.8	98.4	96·7
200		97.5	98.5	98.5	97.0
230		98.0	98.5	98.7	98·2

Although irregularities appear in this table, the final amount of cresylic acid obtained in each case is very much the same.

With mixture 3 it will be noted that a much higher percentage of cresylic acid was obtained at the second stage of the distillation than with mixture 4, although the reverse would be expected. The reason of this is that mixture 3 was distilled much more slowly. At (*a*) the rate was 10 secs. per drop as against 3 secs. per drop at (*b*).

Numerous tests on Lysols of known composition showed that an accuracy of 0·5% was possible, and results can be depended upon to 1%.

The following table gives the results of tests carried out on ten different brands of Lysols purchased haphazard from retail chemists. The first column gives the percentage of cresylic acid as found by the direct distillation method. For purposes of comparison the steam distillation method and the U.S. method were carried out in certain instances. In the last column is given the carbolic acid coefficient as found by the American Hygienic Laboratory method (U.S. Public Health Reports, July 8th, 1921). This method is more reliable than the Rideal-Walker method, since among other things the broth and organism are adjusted to a standard p_H value, and comparable results are obtainable by different workers. The original German Lysol appears to have a coefficient of 1—1·5 by this method:—

Sample no.	Direct distillation method	Jordan and Southerden's method	Chapin's method	A.H.L. coefficient.
1	47·5, 47·5, 48	46·1	41·0	1—1·5
2	48·0, 47·6	46	40·3	1·5—2·0
3	42·75, 43·0, 44·0	42·2	--	1·0—1·5
4	48·2, 50·0	51·5	40·8	2·5—3·0
5	50·0*	--	—	1·0—1·5
6	49·8	58·0	--	1·5—2·5
7	49·8, 50·0	42·0	45·3	3·75—4·0
8	47·5, 43·9†, 44·0†	49·6, 49·0	47·6	1·0—1·5
		42·5, 44·2	40·4	1·0—1·5
9	47·5, 48·0	44·6	36·0	2·0—2·5
10	Separation not possible	2·0	Less than 3·0	Less than 0·25

* American brand. Certified less than 10% water.
† The same brand, but from a different origin of manufacture.

An examination of this table shows that there is a pressing need for an "official method" for the determination of cresylic acid in Lysols. The method described depends for its accuracy on the fact that the Lysol contains approximately 40—50% of cresylic acid; its accuracy becomes less as the cresylic acid falls below this figure. The Lysols examined appear to be of higher quality than those studied by Jordan and Southerden, who found an average of 40% in 10 samples—one as low as 35%.

Apart from the cresylic acid content of Lysols, there are other considerations, viz.: (*a*) quality of cresylic acid or tar acids; (*b*) quality and quantity of soap present; (*c*) the carbolic acid coefficient.

The various substances which constitute commercial cresylic acid naturally have different germicidal effects. When tested in aqueous solution, for example, their differing solubilities cause differing results (*cf.* Lunge, "Coal Tar," 5th Ed., p. 77); apparently the Prussian Ministry which ruled in 1909 that Lysol should contain cresylic acid with no *o*-cresol* was guided by some such considerations. Experiments carried out by the author showed that when the isomeric cresols are made into Lysols with soap solution, their germicidal powers are approximately equal. Thus in one experiment, four Lysols were made up containing respectively 50% of pure *o*-cresol, *m*-cresol, *p*-cresol, and fractionated commercial cresylic acid, 35% of pure neutral soap being used in each. The American Hygienic Laboratory test was applied to each with the same culture (*B. typhosus* in 3% "Lemco broth" of p_H 6·7). In every instance results were positive at dilutions higher than 1 part of Lysol in 300 of water and negative at dilutions below 1 part in 200 for intervals of time from 5 to 15 minutes. In fact, the only differences found were at a dilution of 1 part in 250.

It may be mentioned that with six of the makes of Lysol examined, a Rideal-Walker carbolic acid coefficient was given on the label. There is no reason why a coefficient should not be stated in every case.

A large amount of work has been done in Germany on the influence of various soaps in Lysol (*cf.* Neufeld and Kahlbaum, Z. Hyg., 91, 21 for bibliography). Against a pure culture of any particular organism various soaps must have differing effects, as the physical properties of the colloidal cresol solutions are different. In practice no one is likely to contend that Lysol should be made of a particular soap.

The presence of soap in Lysol ensures that the cresol is brought to the part being disinfected, and is also of importance from the cleansing aspect. Consequently a stipulation might well be made that the "inert matter" in Lysol should not fall below a definite figure. This is the American custom, and it ensures that a product does not contain the maximum amount of water although complying with the requisite of 50% cresols.

In the method of analysis described above, it is easy to arrive at an approximate figure for the fatty acids present. If the distillation is carried out in a tared flask it is only necessary to weigh the residue after distilling off the cresols.

Arising out of the work described above, it is recommended that:—(1) An article described as "Lysol" should have a recognised composition; (2) the amount of water present should not exceed a certain figure (say 15%); (3) the product should be labelled with its "carbolic acid coefficient;" (4) an official method of analysis should be agreed upon.

Vol. XLIII., No. 16] TRANSACTIONS April 18 1924.

SILICA GEL AS AN INDUSTRIAL ADSORBENT.*

BY E. C. WILLIAMS, M.SC., F.I.C., M.I.CHEM.E.

A considerable amount of attention has been drawn in this country during the past year to the industrial use of silica gel as an adsorbent for condensable vapours from gases and as a refining agent for liquids, in particular for the refining of petroleum oils. It is proposed to deal mainly with the possibilities of its employment for the recovery of the benzene hydrocarbons from coal gas or coke-oven gas for use as a motor spirit. In view of the complex nature of coke-oven gas and the impurities which it contains, this is probably one of the most severe tests to which any solid adsorbent process can be subjected.

The work reported in this paper was carried out on behalf of the Joint Research Committee of the National Benzole Association and the University of Leeds, and it is by the permission and courtesy of that Committee and of the Executive of the Association that the results obtained are now made public. At the time when this work was commenced some two years ago, proposals had already been made in America for utilising the known adsorptive properties of silica gel for industrial purposes and patents for its manufacture and use had been taken out in the names of Patrick and others. We had no evidence, however, that any successful industrial process had been worked out or indeed that the problems of benzol recovery had been investigated at all. It was decided to investigate the problem from the beginning, and the conclusions arrived at are therefore independent of any claims put forward by the American Corporation, who are now developing the industrial applications of this substance.

As the use of inorganic gels is somewhat novel in industrial practice, a short review of their mode of preparation and properties may be desirable. It is well known that when certain hydroxides are precipitated, flocculent or gelatinous precipitates are obtained. Copper, iron, and aluminium hydroxides are typical examples, as also is silicic acid when precipitated from solutions of soluble silicates by mineral acid. Graham first showed in 1861 that by mixing with vigorous agitation a 10% solution of sodium silicate with a 10% solution of hydrochloric acid, the acid being in excess, it was possible to obtain a clear colloidal solution of silicic acid from which the dissolved electrolytes could be almost completely removed by dialysis. The silicic acid immediately after formation probably forms a true solution; it is able to diffuse through a parchment membrane and shows vapour pressure lowering and osmotic pressure. Within a few minutes, however, the molecules of silicic acid coalesce to form larger aggregates which exhibit the properties of a true hydrosol. Graham observed that such a solution, on standing, coagulated to a firm, elastic jelly which, on drying in a desiccator over sulphuric acid, gave a hard glassy mass of great lustre. Little further work was done until the years 1890 to 1900, when van Bemmelen, in a series of studies upon the vapour pressure relationships of various hydrated oxides, made an exhaustive examination of the vapour pressure phenomena displayed by silica gel and observed the physical changes which take place in the gel during the process of drying. He showed that, on drying, the hydrogel contracted to a hard glassy porous mass which was able to absorb water and other vapours. He investigated particularly the effect of the concentration of liquid from which the gel was prepared and the time taken for the drying of the gel, upon its porosity and adsorptive power (Z. anorg. Chem., 1897, **13**, 239; 1898, **18**, 117). Zsigmondy, Butschli, Bachmann, Anderson and Patrick have also investigated the structure of silica gel by ultra-microscopical methods or by the determination of vapour pressures of liquids adsorbed by the gel.

The fact that a jelly containing as many as 100 molecules of water to each molecule of SiO_2 is a moderately stiff elastic structure indicates some strong bond between the silica and water. Cases of two liquids forming an apparently solid structure, *e.g.*, butter; or a liquid and gas, *e.g.*, whipped cream or white of egg, are well known and may be explained on the basis of a cellular or honeycomb structure. Silica gel is unlike these in that the water in the gel can be completely replaced by other liquids or may be completely removed without affecting the characteristic structure of the gel. These properties preclude the possibility of a honeycomb or cell-like structure and direct ultra-microscopical examination has failed to establish definitely what the true structure is. It may conceivably consist of threads of silica particles intertwining indiscriminately and in all directions after the fashion of the threads in a ball of cotton wool; or may, as Zsigmondy represents it, be simply a formless collection of particles of silica held together by the adsorption of water at their surfaces. Either of these views would account for the open structure which, as will be seen, the gel must possess.

Van Bemmelen (Z. anorg. Chem., 1898, **18**, 140) investigated the physical changes which occur when silicic acid jelly is gradually deprived of water. Table I (reproduced from his paper) records the volume and specific gravity changes during dehydration. The last column shows the calculated specific gravity of a jelly containing the proportions of water and silica indicated in the first column, whilst the third column shows the specific gravities actually observed.

* Read at a meeting of the Chemical Engineering Group on March 7, 1924.

TABLE I.

Mols H_2O per mol. SiO_2	Volume of gel	Specific gravity Observed	Specific gravity Calculated
122	29	1·00	1·01
75·7	18	1·02	1·02
45·2	11	1·04	1·04
23·2	4	1·08	1·09
11·3	3	1·14	1·14
2·8	1	1·40	1·41
2·2	0·86	1·51	1·49
1·7	0·75	1·58	1·56
Transition point			
1·00	0·73	1·40	1·72
0·39	0·73	1·21	1·93
0·30	0·73	1·17	2·00

It will be seen from column 2 that the gel rapidly contracts as water is removed, until a point is reached at which the water content is some two molecules per molecule of SiO_2. Up to this point the decrease in volume of the gel exactly corresponds to the volume of water removed, as is shown by the agreement between the observed and calculated specific gravities. The particles of silica have, therefore, gradually closed together while the spaces between them have remained completely filled with water. After this point, however, dehydration does not cause further contraction. The silica particles have assumed a final rigid structure and further dehydration leads to the driving out of the water from between the silica particles, the spaces being filled with air as rapidly as the water is removed. With the first entry of air the gel loses its transparency and becomes chalky white in appearance, due to the refraction and reflection of light from the minute air bubbles, breaking the continuity of the water within the gel. As dehydration proceeds still further practically the whole of the water is removed and the interspaces become filled with air and the gel regains its transparency. The gel in this final form is a hard, clear, lustrous substance, to all appearances like fragments of broken glass, and it is in this form that it is employed as an adsorbent.

It is not necessary to enter more deeply into the fascinating studies which have been made upon the structure of silica and other gels. The essential point is that, by the formation of the hydrated gel, silica is obtained in a state of extreme subdivision widely dispersed in a water medium, the particles being held in a more or less rigid structure. On dehydration, either in a desiccator, or by heating, the gel contracts, the particles close together until finally they can contract no further. The interspacial water is then driven off, leaving a highly porous, but optically homogeneous, substance. The determination of the actual size of the pores is a matter of some difficulty. The fact that they are beyond the resolving power of the ultramicroscope indicates a diameter of the order of some $10 \mu\mu$, while determinations made by Anderson (Z. physik. Chem., 1914, **88**, 191) of the vapour pressures of liquids held in the pores lead to a value of 2·5 to 5·5 $\mu\mu$. Anderson's method is, however, open to some criticism in so far as his calculations are based on the assumption that the vapour pressure of liquids in such minute pores obeys the same laws as apply to liquids in bulk.

Van Bemmelen (Z. anorg. Chem., 1897, **13**, 239) further investigated the influence on the porosity and adsorbing power of silica gel, of variation of such conditions as the concentration of liquid from which the gel was coagulated, and the time taken for the drying of the gel. Either of these factors would tend to affect the size and nature of the silica aggregates formed, and therefore the structure and porosity of the dried gel.

The nature of adsorption by porous bodies.

Almost every solid surface, whether porous or otherwise, is able to adsorb small amounts of gas or vapour. The extraordinary difficulty, for example of removing the last traces of moisture from the surface of a glass vessel is well known. The amoun of vapour adsorbed by a given weight of substanc must clearly be greatly enhanced when the substanc exposes so vast a surface as does the silica in silic gel. (The surface of a cube of 1 cm. edge is 6 sq. cm. but if that cube were broken up into cubes of 10μ, edge, the surface exposed would be 600 sq. metre or some 6500 sq. ft.) This type of adsorption is purely surface effect, and is dependent upon definit forces of attraction between the molecules of th solid and the molecules of the gas or vapour. Thes forces are generally assumed to be of a chemical c polar origin and lead to a definite orientation of th adsorbed molecules at the surface of the soli It is therefore to be expected that adsorption of th type will be affected by the molecular arrangement the vapour molecules or of the molecules of th adsorbent, and that adsorption will be largel selective. Such adsorption is met with particular in the case of certain forms of active charcoal, ar is in many cases a very desirable property from th industrial standpoint.

A second type of adsorption, which may com into play when a highly porous adsorbent is use is purely physical in nature. When a capilla glass tube is dipped into water, or other liquid whi wets the surface of the glass, the water rises in t capillary to a height dependent upon the radius the tube and the surface tension of the liquid. T vapour pressure of the liquid over the meniscus the tube is less than that over the same liquid co tained in an open vessel and for any diameter of t tube, the vapour pressure of the liquid contained it may be calculated. (The reverse calculation is t basis of Anderson's determination of the pore diame already mentioned.) It is evident that if a su ciently fine capillary tube is brought into an atn sphere of condensable vapour in which the vapo pressure of the vapour is higher than that wh would be in equilibrium with the liquid contain in the capillary, then a partial condensation of vapour in the capillary will take place. Silica may be regarded as a mass of such fine capillar Since these capillaries are formed by the juxtaposit of silica particles they are not of the same diame throughout. The capillaries themselves are proba wedge-shaped and of different sizes. It is possi therefore, to consider the pore space of any fragm of gel as forming a single long wedge-shaped capill

ich in the presence of a condensable vapour will :ome filled with liquid from the apex of the wedge :wards, until a point is reached at which the .meter of the capillary is such that the vapour ssure at the liquid meniscus is equal to that the vapour in the surrounding atmosphere. The .ount of vapour adsorbed is therefore a function the vapour pressure. It is evident that it must o be a function of the temperature. Change in her vapour pressure or temperature alters what y be called the "ease of condensation" of the vapour, l it is more convenient, as pointed out by Patrick, express such case of condensation in terms of a gle condition of the vapour instead of in terms of o. This single condition, which determines the gree of adsorption, has been defined by Williams l Donnan (Trans. Faraday Soc., 1914, 167), who owed from a thermodynamic analysis, that if the io of the actual vapour pressure of a vapour the saturated vapour pressure is equal to unity, amount of vapour adsorbed is a finite maximum d is independent of temperature. Patrick has med this ratio of partial pressure to saturated ssure, the "corresponding pressure" of a vapour, d has shown that in the case of adsorption of phur dioxide by silica gel the same amount of is taken up whatever the temperature, provided that the corresponding pressure is equal to y. The amount of vapour adsorbed by a given s of gel is so great that it must be regarded as densed in the liquid state. It is therefore prefer-, in comparing the adsorption of different vapours consider adsorption in terms of liquid volume, ner than as weight or volume of vapour. Bach-an (Z. anorg. Chem., 1913, **79**, 202) showed that n silica gel is exposed to the saturated vapour of er, benzene, or chloroform, the same liquid volume each vapour is adsorbed, and furthermore that volume is equal to that taken up when the gel mmersed in the respective liquids. The finite ximum adsorption which takes place when silica is exposed to a vapour at a corresponding pressure al to unity represents therefore a complete filling the pore spaces of the gel, and the principle of lliams and Donnan can in this case be extended read: "that for corresponding pressures equal mity the same liquid volume is adsorbed, whatever vapour or whatever the temperature."

'he adsorption of vapours by silica gel is regarded many workers as a purely physical capillary nomenon of the type described above, but there several observations which do not agree with point of view. It is not intended in this paper, vever, to enter into the theory of the mechanism adsorption by silica gel, but rather to deal with e of its industrial applications. For this purpose capillary theory of adsorption presents a useful crete picture of the mechanism by which vapours adsorbed, and is sufficient to explain many of phenomena observed.

'he immediate problem before the National nzole Association was the possibility of using solid orbents in lieu of wash oil for the recovery of the densable hydrocarbons from coal gas and coke-oven gas. The use of active charcoal and various inorganic gels was considered, and silica gel was chosen for first investigation because of certain definite advantages which it appeared likely to possess. Coke-oven gas contains many impurities likely to affect or destroy the adsorptive power of solid adsorbents, chief amongst which are the presence of tar fog in the form of a fine suspension; the vapours of high-boiling hydrocarbons, or of compounds which tend to polymerise to high-boiling resinous substances in the body of the adsorbent, which would not be removed by the usual processes of distillation; and sulphur compounds, including hydrogen sulphide, which might act upon the material of the adsorbent. The possibility of contamination with resinous organic matter demands that the adsorbent should be able to withstand heating in an oxidising atmosphere to a temperature sufficient to burn off such organic compounds and the deposit of carbon which is formed from them in the pores of the adsorbent during the initial period of heating. Ferric hydroxide gel, a substance of similar structure to silica gel was found to be unable to resist the high temperatures involved; it broke up completely to a finely powdered oxide which showed no adsorption capacity; there is also the danger that such a metallic hydroxide gel, even if able to withstand high temperatures, would be acted upon by the hydrogen sulphide in the gas. Active charcoal is at a disadvantage when heating in an oxidising atmosphere to a temperature of about 600° C. is involved; this disadvantage might be obviated by carefully purifying the gas before passing it over the charcoal. Silica gel is commendable on account of its chemical inertness and its ability to withstand high temperatures. These two factors counteract to a great extent the undoubted superiorities which active charcoal possesses, particularly its greater adsorptive power for vapours at low concentrations and its selective adsorption of hydrocarbons in preference to water vapour.

In the investigations undertaken, adsorption efficiency and capacity were measured by the dynamic method rather than by the static method adopted by van Bemmelen, Anderson and Patrick, since this method is more closely allied to conditions which would obtain in large scale practice. After carrying out these investigations we became acquainted with a paper by E. B. Miller (Chem. and Met. Eng., 1920, **23**, 1155, 1219, 1251), in which the examination of mixtures of air with benzene, ether, acetone, and other solvents by the dynamic method is described and, in so far as our results cover the same ground, they are in complete agreement with Miller's.

The silica gel used was prepared by the method recommended by Patrick (J. Amer. Chem. Soc., 1920, **42**, 951) and preliminary experiments were made to determine the efficiency and capacity of the gel for the adsorption of benzene from mixtures of air and benzene.

The apparatus is shown in Fig. 1. A current of air was drawn through a calcium chloride drying tube, A, a calibrated flow-meter, B, a three-bulb saturator, C, containing benzene, the U-tube, D, contain-

ing the gel under examination, and two additional guard tubes (E, F) also containing gel and serving to determine the amount of benzene passing D. The release valve, G, ensures a steady suction through the apparatus.

It will be seen that benzene is adsorbed almost quantitatively for a period of three hours, during which time the gel takes up 40% of its own weight of benzene. After three hours the efficiency of adsorption falls off rapidly to zero, the gel becomin

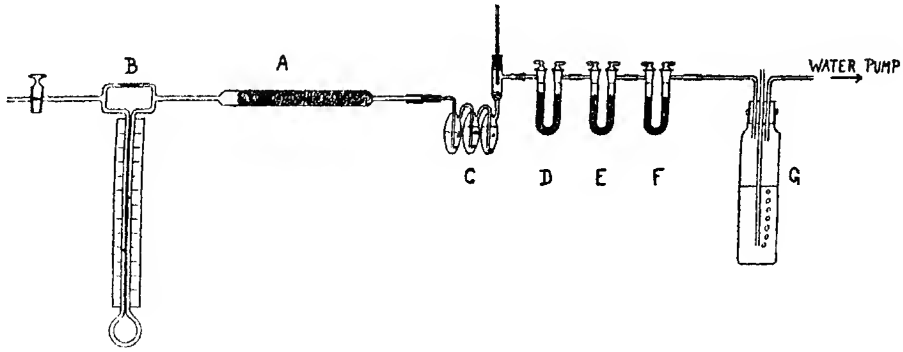

FIG. 1.

The gel tube, D, contained 12·606 grams of gel, and air was drawn through the apparatus at a rate of 100 c.c. per minute. The saturator, C, and the three U-tubes were weighed at frequent intervals, and it was found that the whole of the benzene lost from C

was recovered in the three gel tubes. In Table II the adsorption by D only is shown. The data from this table are plotted in Fig. 2.

saturated at 55·4% benzene content. (It is interesting to note that the gel used in this experiment had been heated 30 times to 600° C. for a perioc of one hour, and its adsorptive capacity had no appreciably fallen from the value initially observed.

This adsorption of 55·4% of benzene was fr air saturated with benzene. The efficiency of adsor tion from a gas containing benzene at a concentrati corresponding to that actually present in coal gas coke-oven gas was next examined. The content benzene in coal gas may be taken as approximate 0·8% by volume, corresponding to about 8 saturation.

The apparatus was essentially as in Fig. 1, wit the exception that a second metered stream of dr air could be mixed, by means of a connexion, wit the stream of air saturated with benzene. adjusting the proportion of air added, any desire concentration of the mixed gas was obtainable.

The figures of Table III and curves in Fig. 3 ow the efficiency and capacity of two gel tubes laced in series in a gas stream containing 0·84% of enzene. The first tube contained 5 grams and the cond 9·5865 g. of gel; the rate of gas stream was 82 c.c. per minute, giving a time of contact of 2 to 3 econds in the first tube and about twice that period n the second.

'he results show a saturation value of the gel at C. of 13·7% by weight, while 11% is taken up 00% efficiency. These are the adsorption values ch would be expected when working on an rage coal gas, provided that the adsorption were affected by other factors.

'ables II and III show the adsorption obtain- from a gas containing 9·5% and 0·84% of zene. The adsorption capacity of gel in gases f intermediate concentration is not of immediate nterest from the standpoint of recovery from coal as, but it can readily be determined. Table IV and

The above experiments were made with simple benzene-air mixtures. The case of coal gas or coke-oven gas is not so straightforward. Apart from substances which may foul the gel and so reduce its activity, there are a number of different vapours, each with its own particular partial pressure and its own corresponding pressure, p/p_0 as defined by Williams and Donnan (see page 99 T).

The partial and corresponding pressures of some of the main condensable vapours in normal coal gas are found to be as follows :—

TABLE V.

	Partial pressure (p) mm. Hg.	Saturation pressure (p_0) mm. Hg.	Corresponding pressure p/p_0.
Pre-benzol	0·165	195	0·0009
Benzene	5·880	60	0·0980
Toluene	1·158	14	0·0825
Xylene	0·528	4	0·122
Naphthalene	0·019	0·03	0·65
Water	12·780	12·78	1·00

The figures for pre-benzol, benzene, toluene, and xylene are those given by T. F. E. Rhead (Gas J., 1917, **137**, 207) as representative of a normal coal gas at 15° C. The naphthalene figure corresponds to a content of 6 grains per 100 cubic feet; in practice even higher figures may be obtained. The water figure is based on the assumption that the gas is saturated. All the saturation pressures are for 15° C. It is clear from the principles of capillary adsorption discussed on p. 99 T, that if the adsorption of these constituents could be considered independently, the saturation capacity of the gel would be greatest in the case of water which is present at a corresponding pressure equal to unity, and would, therefore, be taken up by the gel to the extent of approximately 60% by weight (55% of benzene was taken up from a saturated benzene vapour, and the same volume of water would be adsorbed from a saturated water vapour). Naphthalene would come next as having the next highest corresponding pressure, then xylene, benzene, toluene, and pre-benzole in rapidly decreasing amounts. This is what would occur if a gas were passed containing each of these constituents singly at the concentrations mentioned, but obviously a vastly greater volume of gas would have to be passed in the case of naphthalene than, say, in the case of benzene or water, since the actual concentration of naphthalene in the gas is so small. What, then, will happen when a gas is passed containing all these constituents together? Examining the case where two only of the vapours are present, and choosing two which have widely different partial and corresponding pressures—benzene and naphthalene—it will be assumed for simplicity that the naphthalene is present to saturation in the gas, which is a possible condition. The corresponding pressure of naphthalene is then equal to unity, and if sufficient gas were passed, the naphthalene would be adsorbed by the gel to the extent of some 70% by weight (benzene at $p/p_0 = 1$ gave 55%: this multiplied by the ratio of specific weights of naphthalene and benzene, 1·15/0·88, gives the weight of naphthalene adsorbed at $p/p_0 = 1$). Thus, in order to saturate 10 g. of gel with naphthalene, it would be necessary to pass 7 g. of naphthalene, which at 9·4 grains per 100 cu. ft. corresponds to 1150 cu. ft., or 32,500 litres. In the meantime, however, the gel has long reached its saturation point with respect to benzene. This point, for a partial pressure of 6 mm. at 15° C., is approximately 14% of the weight of the gel, and is, therefore, reached when 1·4 g. of benzene, or 50 litres of gas, have been passed. At this point the naphthalene passed amounts only to 0·0108 g. There is a question now of what will take place if the gas continues to pass after the saturation poin to benzene is reached. Clearly, no more benzene wi be adsorbed by the gel, but will the naphthalen simply fill up the balance of pore space left to it b the benzene, or will it displace the benzene alread there? Where, as in this case, there is presumabl no question of preferential surface adsorption comin into play, the answer is not self-evident, and ther is no published work which gives a satisfactor reply.

In order to investigate this point, which appeare likely to be of importance in the recovery of benz from gases, it is necessary to consider adsorptio from a gas containing two condensable vapou whose separate distribution in the gel can be dete mined at frequent intervals. Working on a sma laboratory scale it was impossible to use, say, benzer and toluene, or benzene and xylene, as the adsorbe vapour would have to be distilled out of the gel the completion of each time interval before an analys could be made, and as only a fraction of a gram collected during each interval, this would be i possible.

As the adsorption by silica gel is supposedly purely physical phenomenon and not dependent the chemical nature of the vapour, it was n necessary to restrict attention to hydrocarbo Sulphur dioxide or ammonia might be used as second vapour in conjunction with benzene, as th would be easily distinguished from benzene a separately traceable in their adsorption relatio Actually, water vapour was chosen as being n only separately traceable, but also a material c stituent of coal gas, and one the action of whi will have to be considered. We have the followi data:—

Partial pressure of benzene in gas	6·0 m
Partial pressure of water in gas	12·8 m
Volume of liquid water from 22·4 litres vapour	18 c.c.
Volume of liquid benzene from 22·4 litres vapour	89 c.c.

The volume of water vapour in the gas is 2·13 tin that of benzene vapour; on the other hand, a gi volume of benzene vapour yields five times as m liquid volume as an equal volume of aqueous vap If, therefore, we express the ratio of benzene to w in the gas as volume of liquid condensates, whic the important point from the view of adsorpti we have benzene : water = 5 : 2·13 or 2·35 : 1.

This is a similar, though less extreme, case to t of benzene and naphthalene, discussed previou The benzene, although not capable, like water, of approaching the maximum saturat value (on account of its low corresponding pressu is yet present in considerably greater proportion, liquid volume, than the water, and is, theref able to enter the gel freely in the first stages adsorption before sufficient water has arrived exclude it—assuming for the moment that the vap of the higher corresponding pressure does tend exclude or drive out that of the lower. It is imposs to forecast what should occur in such a mixt and experiments were carried out to test the ab points.

Adsorption of mixed benzene and water vapours.

A gas containing both benzene and water vapour n known concentrations was prepared by mixing two netered streams, one having passed through a water aturator and the other through a benzene saturator, s shown in Fig. 5. Each stream was dried in a gel. The gas mixture contained 0·86% of benzene and 1·85% of water by volume with partial pressures 6·5 mm. and 14·2 mm. respectively. The temperature of the saturator and adsorption tubes was 18° C. The saturation pressure of water vapour at 18° C. is 15·46 mm. The gas was therefore not

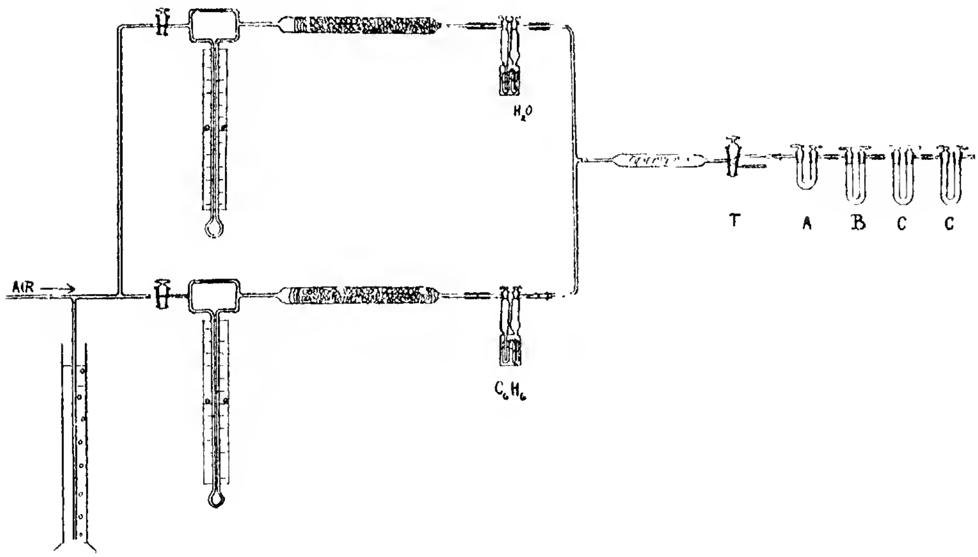

FIG. 5.

ng calcium chloride tube before passing through ie saturator. After mixing in an intermediate essel, the gas passed through: A, a small tube conaining 3·708 g. of gel; B, a tube containing granular alcium chloride; C, two guard tubes filled with silica fully saturated with water. The mixed gas was passed through the adsorption tubes for 21·7 hours at a rate of 135 c.c. per minute. By periodic weighings of the water and benzene saturators, the gel tube, A, containing the gel under examination,

the calcium chloride tube, and the final guard tubes, a determination of the amounts of water and benzene adsorbed by A at any moment was made. The results are given in Table VI and are plotted in Fig. 6. (The determinations for the first three points of the curves in Fig. 6 are not shown in Table VI; they were obtained from an independent experiment under exactly similar conditions.)

It is evident, therefore, that the F vapour is a factor to be seriously cons... ration point problem of recovering benzene from gas. ...zene will only prevents the benzene attaining the ne... saturation value corresponding to its vapour pressure, but also, in the event of the gas being passed over the gel in too great a volume, leads to a complete washing out of the benzene initially adsorbed, even though

FIG. 6.

Curve A shows the adsorption of water, expressed as per cent. weight of the gel. Curve B shows the adsorption of benzene in the first gel guard tube, and is therefore a check upon the adsorption which would have been obtained had the gas not contained water vapour. Curve C shows the actual benzene adsorption from the wet gas. It will be observed that in the initial stages benzene was taken up to the extent of 7·92% of the weight of the gel, but as the passage of gas was continued, the benzene was gradually displaced by water, until finally no benzene remained in the gel. The water, on the other hand, gradually accumulated in the gel, and at the completion of the experiment was still being rapidly adsorbed. A further proof of the fact that the benzene is displaced is shown by the figures in the last column of Table VI, from which it is seen that during every interval after the first two hours, more benzene was recovered in the guard tubes than was lost from the benzene saturator.

the concentration of benzene in the gas remai constant. The explanation probably lies in t relative ease of wetting of the silica surface by wat and by benzene. If the silica surface is coat preferentially by a film of water, the benzene is n able to wet the surface, and therefore depends for i retention upon its power to wet, or be adsorbed b the water film. If benzene is adsorbed less strong at a water face than at a silica face, then as the wat film develops over the surface of the silica, benze must be driven out, whether the adsorption is regard as a molecular surface adsorption or as a pure capillary condensation.

The next step to be taken was the ex... stages of the adsorption of hydrocarbons from ... examination gas. A supply of purified town gas w... that actual coal the mains of the Leeds gas works at ... was drawn from ately after the iron oxide pur... a point immedi stream of this gas was pass... ifiers. A metered six adsorption tubes, carri... through a series of each containing 12 grams of

Adsorption of benzene just commenced to pass the A gas co... contents of each tube were distilled know... and collected in a graduated receiver ... to -10° C. The quantities obtained on such a le were too small to permit of an accurate analysis, ; were sufficient to show the selective adsorption he various constituents of the gas along a column dsorbent. The approximate analysis is expressed Table VII below, in terms of water, benzene, and iene. The small amounts of hydrocarbons with ling points higher than toluene and lower than zene have been neglected.

TABLE VII.

orption of water and hydrocarbons from coal gas in a six-section column

'I	0·0	1·10	100	0	79·5

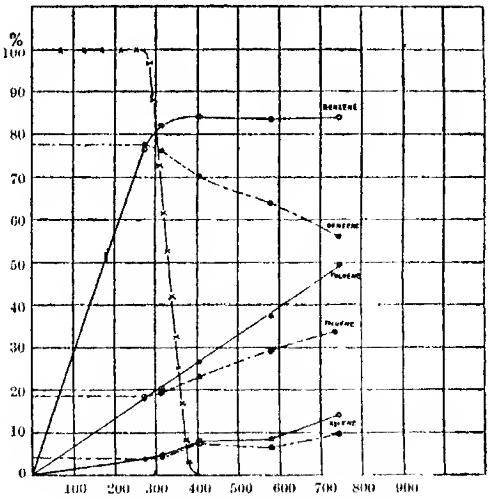
This volume includes a drop of the distillate from the vious tube.

t is evident from these figures that a considerable ;ree of fractional adsorption takes place, and that water and higher boiling hydrocarbons are con- trated at the entrance of the column of gel. leed, by using two adsorption chambers, the second taining twice as much gel as the first, it would be sible to recover 60% of the total hydrocarbon he gas (or 76-77% of the total benzene in the gas) practically pure benzene.

'he coal gas used in the above experiment con- ied 0·80% of benzene and 0·19% of toluene luding xylene and naphthalene).

Experiments were next carried out to determine, re accurately than was possible in the small six- tion column just described, the efficiency of orption and the composition of the recovered lrocarbons when varying amounts of gas were sed over a constant weight of silica gel. The ults of these experiments are summarised in ble VIII and are plotted in Fig. 7. The adsorption s carried out at a temperature of 14°, and the gas umes passed are expressed as litres at N.T.P. per) grams of gel.

'he first determination recorded, 273 litres of gas 100 grams of gel, is for an adsorption which was stopped exactly at the break point to benzene. For smaller quantities of gas it has been shown that all the benzene and all the other higher boiling hydro- carbons are quantitatively recovered. The important point therefore to be observed, where complete recovery of useful hydrocarbons is intended, is this break point to benzene. The still lower boiling constituents in coal gas, of which carbon bisulphide is the chief, are present at such small partial pres- sures and corresponding pressures (see Table V), that the amounts adsorbed are practically negligible. There is, therefore, in the hydrocarbon mixture recovered by silica gel none of the "pre-benzol" which must be so carefully fractionated from the spirit recovered by oil-washing processes.



Vol. of gas passed per 100 g. of gel.

FIG. 7.

The recovery figures corresponding to a passage of 273 litres of gas represent, therefore, a maximum recovery of the hydrocarbons valuable as motor spirit. Up to this point all such hydrocarbons are quantitatively adsorbed, and the proportions of the various hydrocarbons in the recovered mixture are therefore identical with the proportions in the original gas. If a greater volume of gas is passed over the

TABLE VIII.

orption of hydrocarbons from coal gas by silica gel, showing the effect of ratio of gas volume to weight of gel on the degree of adsorption, distribution of individual hydrocarbons, and composition of the recovered benzol.

Expt. no.	Volume of gas per 100 g. of gel Litres N.T.P.	Total hydro-carbons adsorbed as % weight of gel	Distribution of hydrocarbons as per cent. weight of gel: Benzene	Toluene	Xylene	Composition by volume of liquid hydrocarbons recovered: Benzene %	Toluene %	Xylene %
..	273	9·84	7·65	1·80	0·39	77·5	18·5	4 0
..	315	10·70	8·20	2·04	0·46	76 2	19·45	4 35

same amount of gel, benzene begins to escape at the exit of the adsorber. The higher-boiling hydrocarbons do not, however, reach their break points for some considerable period later, with the result that the composition of the mixture of hydrocarbons recovered from the gel gradually changes, the percentage of benzene becoming smaller and that of the constituents of higher boiling point less. This is shown clearly by the broken curves of Fig. 7. From this series of curves it is possible to determine what proportion of gel to gas must be employed in order to secure any desired composition of hydrocarbons from the adsorption units. In order to secure complete "stripping" it is not possible to pass more gas of the composition under consideration than 273 litres per 100 grams of gel, and at this point the adsorption expressed as per cent. weight of the gel is 7·65% of benzene, 1·80% of toluene, and 0·39% of xylene (including higher-boiling hydrocarbons). The total effective adsorption of hydrocarbons is, therefore, approximately 10% of the weight of the gel.

It will be observed, also, that over the range of these experiments, which more than covers the limits within which a commercial adsorption process would be operated, no evidence was found of actual displacement of benzene by water vapour. The benzene having attained its maximum saturation value of 8·4% remained at this value over the whole period considered.

It is therefore practicable to use silica gel for the adsorption of hydrocarbon vapours from coal gas saturated with water vapour. The adsorption capacity for the hydrocarbon is, however, lower than if no water vapour were present, and in the above experiments amounted to slightly less than 10% of the weight of the gel.

The whole of the water vapour must be removed concurrently with the hydrocarbon vapour. This is unavoidable since water vapour is, as has been shown above, preferentially adsorbed.

The actual saturation value for benzene when adsorbed from coal gas is slightly higher (8·4%) than that obtained from the pure mixture of benzene, water vapour, and air investigated in the laboratory and illustrated in Fig. 6. This is to be expected since the benzene in the gel is dissolved in a certain amount of higher boiling hydrocarbons, which tend to lower its vapour pressure.

A very interesting observation from the point of view of motor fuel production was that the mixture of hydrocarbons recovered from the gel by direct distillation was of considerably better quality as motor fuel than the corresponding mixture obtained by scrubbing the gas with wash oil. Apart from the fact that wash oil takes up, under normal working conditions, only some 3 to 4% of its volume of hydrocarbons from the gas, the product obtained on distilling benzolised wash oil with steam (known technically as "light oil") contains, at the low-boiling end of the scale, appreciable amounts of carbon bisulphide, and at the high-boiling end some 5 to 15% of creosote or high-boiling paraffin oils distilled from the wash oil itself. The product obtained from silica gel contains a negligible amoun[t] of carbon bisulphide, and clearly can derive [no] heavy oil from the distillation of the adsorben[t]. Furthermore, the light oil obtained by oil washing is almost invariably yellow in colour, and quickl[y] darkens to a light brown colour. The produc[t] obtained from silica gel, in the experiments described, was colourless, and remained colourless over severa[l] months. This is an important point for the moto[r] spirit producer. It is not proposed in this paper to g[o] into the causes of discoloration of motor spirit, but it is well known that there is frequently a close parallelism between discoloration of the spirit on storage and gum formation in the engine valves when the spirit is used. Drastic chemical treatment of the motor spirit, usually consisting in washing with concentrated sulphuric acid, is normally employed at the present time to remove these objectionable gum-forming constituents. Unfortunately such treatment destroys more than the objectionable constituents which it is intended to remove, and probably one-half to one million gallons of potentially valuable motor fue[l] are destroyed per annum in this country by moto[r] benzol producers alone. Petroleum oil refiners are, on the whole, more enlightened in this respect, an[d] by the development of less drastic refining process[es] have considerably reduced their refining losse[s]. Nevertheless, the loss of valuable petroleum mot[or] spirit by sulphuric acid washing probably great[ly] exceeds the figure given above for benzol.

The fact that the benzol recovered by means [of] silica gel appeared to show no signs of discoloration or resinification on storage was therefore an additional merit in the process, as it held out hopes tha[t] the product would need no further refining treatment. The other outstanding objectionable constituent in motor spirit is sulphur, whether free or combine[d]. In this respect the benzol recovered as describe[d] above did not show any marked superiority over th[e] unrefined benzol as normally produced by o[il] washing, except in so far as it was traceable to [its] freedom from carbon bisulphide. The average sulph[ur] content of the gel recovered spirit was 0·4–0·5[%]. This statement is not in opposition to the claim of t[he] Silica Gel Corporation that the sulphur content [of] many petroleum oils can be reduced to a very l[ow] figure indeed by treatment in the liquid phase wi[th] silica gel. The question of what types of sulph[ur] compounds are removable by silica gel is a compl[ex] one, and it is not proposed to deal with it in th[e] present paper.

The results already indicated warranted a tri[al] of silica gel as an adsorbent for motor benzol pr[o]duction on a larger scale. The main points in favour [of] such an adsorbent in place of wash oil appeared to be :

(1) Adsorption of 10% by weight or about 11·5[%] by volume of hydrocarbons as compared wi[th] 3–4% by volume usually obtained with wash o[il].
(2) Complete recovery of the useful hydrocarbon[s] very rarely obtained with wash oils.
(3) A crude oil free from low-boiling "pre-benzol" and uncontaminated with high-boiling creoso[te] oils, except for the small amount adsorb[ed] from the gas.

(4) The possibility of eliminating all chemical refining processes and particularly the sulphuric acid treatment.

(5) A saving, consequent on (4), of some 5-10% of the crude spirit.

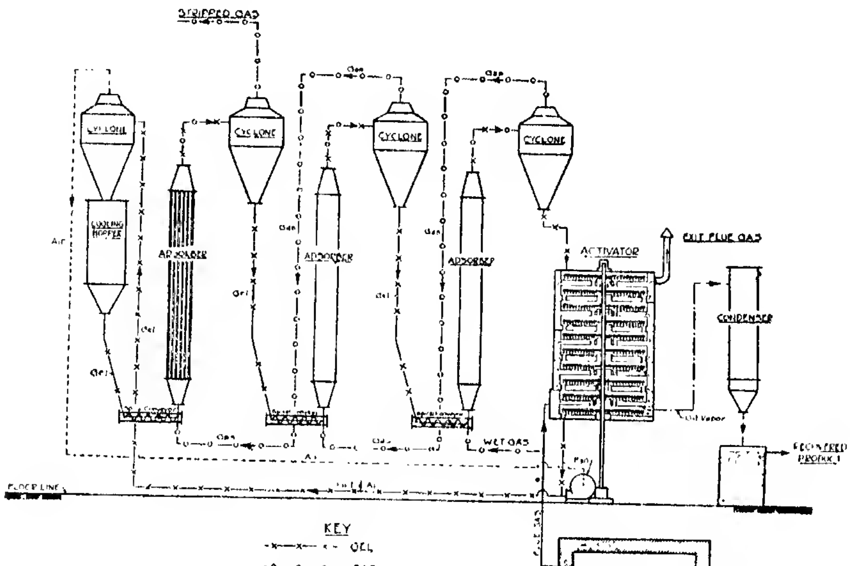
(6) Avoidance of the nuisance and waste arising from the acid sludge produced by acid refining.

(7) A complete removal of naphthalene from coal gas is incidental to benzol recovery. This is of considerable importance to manufacturers of coal gas for town distribution. If desired a very small silica gel plant could be arranged to remove all naphthalene without stripping the gas of benzol.

It was at this stage that we were approached by Mr. J. A. Reavell of the Kestner Evaporating and Engineering Company, the concessionaires of the Silica Gel Corporation, Baltimore, who informed us that they were about to carry out semi-large scale trials on the recovery of motor spirit from coke-oven gases by silica gel adsorption. The National Benzole Association was invited to send representatives to investigate these trials and Mr. Basil Adler and the author were appointed for that purpose. Together with Mr. Reavell they visited America during June and July last, and the remaining portion of this paper is devoted to a description of the trials carried out during that period.

The Silica Gel Corporation had during the past four years been experimenting on the industrial application of silica gel to the recovery of vapours and for the treatment of liquids. For the adsorption of vapours a bed type absorber, consisting of static beds of granular gel, was originally proposed and is still recommended for certain purposes. Where large volumes of gas are to be handled, however, a continuous circulation plant is used. In this case the gel is finely pulverised to about 200-mesh, and is circulated with the gas, which, by means of a pump, is maintained at a velocity sufficient to carry the gel along with it.

Adsorption is carried out in vertical adsorbers consisting of nests of tubes in an outer cooling jacket similar in construction to a tubular condenser. The gas and gel are separated at the top of each adsorber by a cyclone separator. The gel is fed into the gas stream at the bottom of the adsorber by means of a small screw conveyor. In actual practice three such adsorbers are used in series, the gas and gel flowing counter current through the series. In this way most effective "stripping" of the gas and saturation of the gel are secured. After traversing the final adsorber, (the one nearest to the gas inlet) the saturated gel is taken from the cyclone separator by a screw conveyor to the top of the "primary activator." This is in effect a still in which the adsorbed vapours are driven off. It consists of a series of horizontal hearths placed vertically above one another and heated by the flue gases from a gas furnace. The hot gases pass through flues interspaced with the hearths but do not come in direct contact with the gel or distilled vapours. The gel entering at the top hearth is raked slowly downwards from hearth to hearth by means of revolving



Reproduced by courtesy of the Silica Gel Corporation.

FIG. 8.

rakes keyed to a vertical central shaft. The arrangement is very similar to the usual pyrites burner. The gel, completely freed from volatile vapours, is discharged from the bottom hearth into another screw conveyor which carries it to a "secondary activator." This activator consists of a slightly inclined revolving drum heated by means of an external jacket, through which hot flue gases pass. The purpose of this second activator, into which a small volume of air is drawn, is to burn off any non-volatile deposits from the gel. The temperature in the primary activator is maintained at 300°—350° C. and in the secondary activator at 550°—600°. The gel leaving the secondary activator is completely revivified and is returned by means of an air blast, provided by a fan working in a closed cycle, to the gel storage and cooling hopper from which it again enters the adsorption cycle. The coke-oven gas, which passes through the adsorption units in the opposite direction to the gel, is finally discharged from the last cyclone (the first from the point of view of gel flow) and passes through bag filters which remove any gel remaining in suspension and return it to the system.

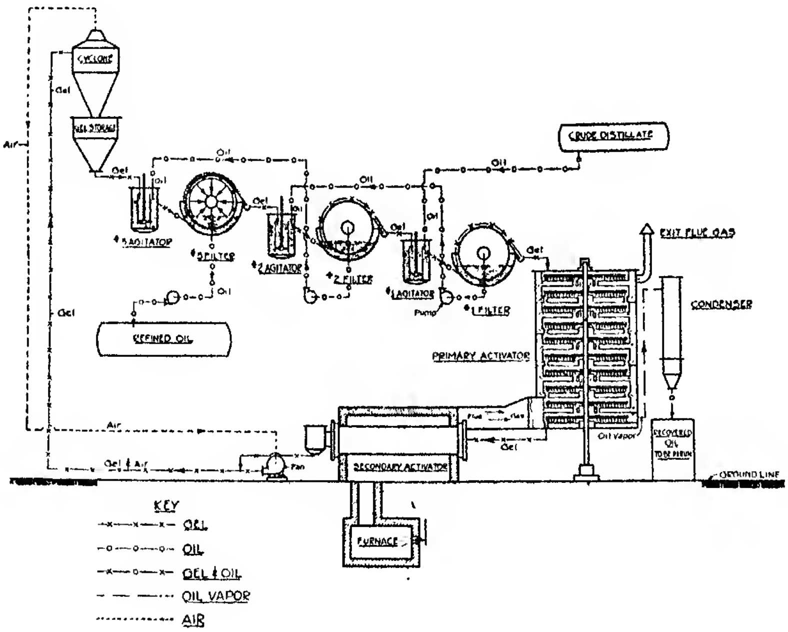


FIG. 9.

The general lay out of the plant is shown in Fig. 8, which is produced by the courtesy of the Silica Gel Corporation. This does not show the horizontal secondary activator, the arrangement of which is shown in Fig. 9.

The adsorption plant erected at the time of our visit was an experimental plant, designed to handle 80—100 cubic feet of gas per minute. This gas was drawn from the mains of the Bethlehem Steel Corporation's coke ovens at Baltimore at a point immediately following the ammonia scrubbers. The coke-oven plant was of the Koppers type and the gas had passed through the usual tar extractors, ammonia saturators, and water-spray coolers; it may therefore be taken as a fair average coke-oven gas.

The amount of recoverable hydrocarbons in the gas was determined by passing a metered volume of the gas through a calcium chloride drying tube and then through a silica gel adsorption tube containing 3 lb. of gel. The adsorbed hydrocarbons were distilled off with steam at 200° C. and measured. This test was shown to be more rigorous than a determination made by the usual method of bubbling the gas through ice-cold wash oil. The content of hydrocarbons in the gas issuing from the adsorption plant was determined in the same manner, and both inlet and outlet tests were made concurrently with a quantitative examination of the hydrocarbons actually recovered in the plant. The results of a typical test are shown below:—

I. Benzol in inlet gas (control)

Total volume passed .. .. = 54·53 c. ft. at 90° F.

Total benzol recovered on distillation .. .. .. = 51·5 c.c.

Benzol content (at 90° F.) .. = $\frac{51 \cdot 5 \times 0 \cdot 2200}{5 \cdot 463}$ Imp. gals. per 10,000 c. ft.

= 2·073 Imp. gals. per 10,000 c. ft.

[. Benzol in effluent gas from plant (control).

Volume gas passed ..	.. = 186·68 c. ft. at 90° F.
Benzol recovered ..	.. = 7·5 c.c.
Benzol content (at 90° F.) ..	$= \frac{7\cdot5 \times 0\cdot2269}{18\cdot668}$ Imp. gals. per 10,000 c. ft.
	= 0·0884 gal. per 10,000 c. ft.

[. Efficiency of adsorption in plant (calculated from control tests).

$$= \frac{(2\cdot073 - 0\cdot0884) \times 100}{2\cdot073} = \frac{1\cdot9846}{2\cdot073} = 95\cdot7\%$$

'. Recovery of crude benzol in plant.
Over the same period as that of the above tests.

Gas treated	.. = 103,505 c. ft. (at 90° F.)
Recovered crude benzol	.. = 10·55 Imp. gals.
Benzol	.. = 1·898 Imp. gals. per 10,000 c. ft.
Theoretical recoverable	.. = 1·9856 gals. per 10,000 c. ft.
Efficiency of recovery ..	.. = 95·6 per cent.

This figure of 95·6% is the average of three shifts ntinuous working; actually one of the shifts erated at 97% efficiency.

The hydrocarbons recovered from the effluent s had an unpleasant odour, and boiled at 76°–78° C. detailed examination of this product was not made, the quantity available was too small; it is almost rtain, however, from its general properties, that ly a small portion of this fraction could possibly considered useful as motor spirit. Estimating is proportion at a liberal figure of 50%, then total loss of motor spirit in the effluent is only 044 gallon per 10,000 cu. ft., and the efficiency adsorption of motor spirit in the plant becomes ·9% of the theoretical.

There is therefore an adsorption of motor spirit om the gas of 97·9% efficiency, followed by a covery of liquid benzol from the gel of 95·6% iciency, giving a total all-round efficiency of covery in the plant equal to 93·6–95% of the iount initially present in the gas.

These results entirely bear out the conclusions rived at in the laboratory as to the excellent covery of hydrocarbons attainable. The temrature conditions of the test were moreover not vourable, the temperature of the inlet gas being ° F. and that of the cooling water 80° F.

The recovered product was, however, not so isfactory. A colourless, non-gumming distillate d been expected from the gel, but the product tually obtained was yellow or yellowish-brown, d neither modifications in the method of working r redistillation of the crude spirit gave appreciable provement. It was evident that the crude spirit uld need further refining. The refining of a uid spirit with gel had already been worked out detail by the Silica Gel Corporation in connexion th the refining of petroleum oils and a continuous itation and filtration plant capable of dealing th 3000 gals. per day had been designed to operate is process. It had been found that a strongly loured gasoline, kerosene or lubricating oil when itated with successive quantities of gel and ered was rendered of excellent colour and pracally free from sulphur. The case of benzol, wever, proved to be somewhat different. Agitation with silica gel followed by filtration did not produce marked improvement in the appearance of the product; but there was this actual improvement in fact, that, if the liquid so treated were distilled, 88–89% came over below 130° C. as a colourless product, while the residual high-boiling 10% was only very slightly coloured. The higher-boiling fraction could also be rendered colourless by a further treatment with gel, and redistillation.

This refining action of the silica gel in the liquid phase appears to be due to the rapid polymerisation of those constituents in the crude benzol which are the cause of discoloration. It is already known that if a crude benzol is allowed to stand for a long period these constituents tend to polymerise spontaneously, and that if such a "matured" benzol is distilled, the high-boiling polymers remain as a gum-like residue in the distillation vessel. Silica gel by adsorbing such constituents increases their activity and accentuates the process of polymerisation, with the result that after a very short period of time the resin-like products can be completely separated by distillation.

The sulphur content of the spirit is not greatly reduced by this liquid phase refining process. The actual content of sulphur was 0·37% in the crude, and 0·28% in the refined spirit. There is therefore greater difficulty in removing the sulphur, whether free or combined, from benzol than from petroleum, for which the Silica Gel Corporation reports almost complete removal of sulphur by simple agitation with gel.

The plant designed by the American Corporation for carrying out the liquid phase refining treatment described consists in its simplest form of a tank fitted with an agitator for mixing the liquid and gel. The mixture from this tank runs to an Oliver continuous vacuum filter from which the treated liquid is withdrawn, while the gel is carried by screw conveyor to a primary and secondary activator of the type already described. In practice, in order to obtain the maximum duty from the gel, three agitating vessels and three Oliver filters are placed in series, the gel and liquid passing countercurrent through the system.

The cycle of storage tanks, agitating tanks, Oliver filters and activators is made gas tight so that losses by evaporation are reduced to a minimum. The actual loss of spirit during this process is confined to the very small amount of the resin forming constituents which are polymerised, the vapour which escapes through the vacuum pump operating the filters, and the vapour which escapes condensation after being distilled off in the activators. These losses amount to 2% as a maximum and probably less than 1% of the spirit treated. They are to be compared with the much greater loss which occurs when a sulphuric acid refining treatment is employed. The general arrangement of a continuous liquid refining plant is shown in Fig. 9.

The crude spirit after agitation with gel and filtration is distilled. This distillation is a necessary stage in the refining process, but it also serves for

The solution was boiled to remove the carbon dioxide and then cooled, a few drops of methyl orange were added, and the solution was titrated with $N/1$ sodium hydroxide until almost neutral, when a few drops of methyl red were added, and the titration with alkali continued until a purplish-red colour became just visible. This gave a very well-defined end-point compared with methyl orange.

The standardisation was also checked against pure dry ammonium chloride, as follows: 5 grams of the ammonium chloride were weighed out and distilled with caustic soda through an apparatus containing a bulb trap, into an excess of the standard acid. The distillate was cooled and the excess of acid titrated against $N/1$ soda first with methyl orange as indicator, the final end-point being determined with methyl red as previously explained.

Throughout the whole of the determinations the end-point was obtained in this way.

After the sulphuric acid had been standardised, the sodium hydroxide was standardised against the sulphuric acid.

Including the preliminary work, over 100 determinations were made, the final table being based on 62 determinations made after the best form of apparatus, and the best way of using it, had been decided. Specific gravities were determined as low as 0·875—a specific gravity very much lower than any previously determined with any degree of accuracy. Lunge's lowest gravity was 0·882 and Ferguson's was 0·886. Every precaution was taken to obviate errors due to wrongly calibrated weights or burettes, frequent standardising of all apparatus used being carried out. The water capacity of the special weighing pipette was found to be the same at the end of the experiments as at the beginning.

All calculations were worked out by two men independently, and were based on the 1923 atomic weights. The actual determinations are shown in Table I.

0·92113	21·45	0·98715	3·00
0·92232	21·12	0·98716	3·00

If these are plotted and the best smooth curve drawn through the points, it will be found that with specific gravities below 0·885 the maximum error is ± 0·05% of ammonia, corresponding to an error in the specific gravity of ± 0·00015; with determinations above 0·885 the maximum error is ± 0·02% of ammonia, corresponding to an error in the specific gravity of ± 0·00007.

Table II. was constructed by reading the percentage of ammonia corresponding to given specific gravities, from the curve obtained by plotting the actual determinations. For purposes of comparison Lunge's table is given side by side with the new table, but it should be pointed out that whereas Lunge's determinations were made at 15° C., the new determinations were carried out at 60° F., so that it was necessary to correct Lunge's figures; this was accordingly done, using Lunge's own temperature corrections.

0·932	18·07	17·99	0·998	0·45	0·45
0·934	17·46	17·38	1·000	0·00	0·00
0·936	16·85	16·78			

A comparison of the two tables brings out the following points:—

(1) For specific gravities between 0·880 and 0·885, the new figures are lower than Lunge's, the maximum difference being 0·33% of ammonia.

(2) For specific gravities between 0·885 and 0·966, the new figures are higher than Lunge's, although the difference is very small.

Upon plotting the results it will be found that for specific gravities below 0·914 a straight line is obtained, whereas above 0·914 there is a slight, but distinct, curvature, the decrease in ammonia content for a given fixed increase in the specific gravity becoming gradually less and less. For example, an increase in the specific gravity of 0·002 at 0·920 corresponds to a decrease in the percentage of ammonia of 0·64%, whereas at 0·960 it is 0·55%, and at 0·990 it is 0·48%. This variation cannot be accounted for by any experimental error, for it is from 20 to 30 times greater than any possible experimental error. It is an interesting fact and one which it is hoped to investigate further at some future date, that this change from a straight line to a curve takes place between the points corresponding to 23·82% and

24·15%, when the composition of the solution may be expressed as $NH_3,3H_2O$, the theoretical ammonia content of which is 23·95%.

In conclusion, the authors desire to express their indebtedness to Messrs. Chance and Hunt, Ltd., Oldbury, in whose laboratories the work was carried out, for having given permission for this paper to be published.

THE USE OF DIPHENYLGUANIDINE AS AN ACCELERATOR OF VULCANISATION.

BY W. M. AMES, M.A., B.SC.

Diphenylguanidine appears to be used to a very considerable extent by rubber manufacturers as an accelerator of vulcanisation, and a study of its properties as such may therefore be of value. There is now a large volume of literature dealing with the numerous organic accelerators, but practically all of it is concerned with the mechanism of the phenomenon of acceleration, and there is little information to assist the manufacturer in the actual use of these materials. In this respect diphenylguanidine, or, as it will be hereafter denoted for the sake of brevity, D.P.G., is no exception.

Kratz, Flower, and Coolidge (J. Ind. Eng. Chem., 1920, **12**, 317) attempted to correlate chemical structure and accelerating effect for a number of substances, of which D.P.G. was one. They further gave data which showed it to be a very active material. Winfield Scott (India Rubber J., 1922, **64**, 605) investigated some of its reactions, and (Ind. Eng. Chem., 1923, **15**, 286) compared it with other guanidines in its behaviour towards sulphur. Regarding its technical use, Weber stated (India Rubber J., 1922, **63**, 795) that it did not produce any discoloration in the finished article, that it could be incorporated without danger of premature vulcanisation in the mixing machine, and that quantities up to ¾% on the rubber could be used with safety. It has been further stated (Le Caoutchouc et la Gutta Percha, 1923, 11816) that the most satisfactory quantity of sulphur to use along with it is from 3% to 5%, and that it produces very flat curing mixings. This rapid survey of the available literature on the subject indicates that the technical use of D.P.G. has perhaps not received the attention which has been given to such well-known organic accelerators as *p*-nitrosodimethylaniline, thiocarbanilide, and hexamethylenetetramine. In order to show how it compares in activity with some of the earlier discoverd accelerators, the first portion of this paper is devoted to a comparison between D.P.G. and *p*-nitrosodimethylaniline, or "accelerene," as it is generally, for convenience, called.

This comparison was carried out first by vulcanising straight test pieces until they reached a standard elongation under a standard load, as indicated in an earlier paper (Anderson and Ames, J., 1923, 136 T). Small equal quantities of D.P.G. and accelerene were incorporated into a control containing rubber and sulphur in the ratio 90:10. Another control containing, in addition, 5% of zinc oxide, had also small quantities of the accelerators added to it. In order to make the quantities of accelerator the same, allowance had to be made for the presence of 33% of water in the accelerene. The six mixings were thus made up as follows, figures denoting parts by weight: (1) Control: Plantation sheet 90, sulphur 10. (2) Control 98, D.P.G. 2. (3) Control 98, accelerene 3. (4) Zinc oxide control: Plantation sheet 45, sulphur 5, zinc oxide 50. (5) Control (ZnO) 100, D.P.G. 1. (6) Control (ZnO) 100, accelerene 1½. The length of time at a temperature of 142° C. necessary to vulcanise test pieces made up with these mixings, so that they reached a standard elongation under a standard load, is shown in Table I. The acceleration is calculated as a percentage of the time of vulcanisation of the appropriate control.

D.P.G. is seen to be an accelerator of practically the same power as accelerene. The presence of zinc oxide does not appear to have much effect on the activity of either, but that is really due to the defects of the method of investigation, which involves comparatively small extensions. Further, the mixings used are probably not suitable for the two accelerators concerned, though they are very useful generally for comparing different materials.

In order to provide a more reliable comparison between the two accelerators, they were incorporated into mixings of plantation sheet 100, sulphur 10, D.P.G. ½, and (A) zinc oxide 5 or (B) light magnesium carbonate 5. A¹ and B¹ are similar mixings containing accelerene, allowance again being made for the moisture present. The four mixings were vulcanised for various lengths of time in the form of slabs, from which ring test pieces were cut for testing on the Schopper machine. The results of these tests are shown in Table II.

Comparison of the tensile figures for A and A¹ shows that, as far as strength is concerned, they are very similar. A¹ vulcanises slightly faster than A,

indicating that accelerene is the better accelerator of the two. It is noteworthy, however, that D.P.G. has a greater toughening effect than accelerene. The result of comparing B and B¹ is somewhat similar, except that the strength of the D.P.G. and magnesia mixing, B, is very poor.

From this preliminary investigation, then, it may be concluded that accelerene and the accelerator under consideration are not very different in activity; but it is also obvious that they are somewhat different in action.

In using such a substance the first necessity is to know the proportions of sulphur and accelerator which will give the most satisfactory results from the point of view of tensile properties, rate of cure, flatness of cure, toughness, and ageing. In the absence of any theoretical guidance, beyond very general statements, the only means of determining the optimum quantities of sulphur and accelerator is to adopt the method of trial and error, which was accordingly done.

To hard fine Para containing 5% of zinc oxide were added quantities of sulphur ranging from 1½% to 15% of the rubber. To these different batches were again added quantities of D.P.G. ranging from ⅛% to 1% on the rubber, so that practically all possible combinations of sulphur and accelerator were investigated. The results are indicated in Table III.

Hard fine Para was used throughout, in order to be reasonably certain of dealing with a normal rubber. The mixings were made up in such a way as to eliminate errors arising from slight deviations in the proper quantity of sulphur, and the rubber was mixed so that the amount required for the experiment would be as nearly uniform as possible. After the mixings had been prepared, they were heated over a range of cures in a "daylight" press, in the form of slabs. The time necessary being in some instances short, the heating was carried out at 135° C., except for the controls and for mixings containing 1½% of sulphur, which were heated at 142°. When the

mixings had been vulcanised, ring test pieces were cut from the slabs and tested on the Schopper machine, giving the tensile data shown in Table III. Each observation of load and final length is the average of three readings. Before proceeding to general conclusions, the properties of each mixing are considered in detail.

No attempt was made to vulcanise a control mixing containing 1½% of sulphur. The addition of ¼% of D.P.G. to such a mixing enables it to be properly vulcanised, although the tensile strength is very poor. It appears to be fully cured in about 3 hours at 142° C. Increasing the D.P.G. to ½% improves the strength slightly, and reduces the time required to 2 hours. The third mixing of the series containing 1% of accelerator possesses quite good tensile strength, and is fully cured in 1½ hours. It is very noticeable that the addition of D.P.G. causes a marked increase in the toughness of the mixing, the increase becoming greater each time the accelerator is augmented. It appears probable that when these mixings are vulcanised beyond their maximum tensile point they become softer. This may be an indication of devulcanisation, due to prolonged heating in the presence of an active accelerator and a small quantity of sulphur.

In the case of the 3% sulphur mixings it was possible to compare the control with the accelerated mixings. The addition of ⅛% of D.P.G. to the stock makes practically no difference to its properties beyond reducing the time of vulcanisation, as indicated by the maximum strength, from 12 hours to 8 hours at 135° C. Further increase in the quantity of accelerator up to ¼% ensures an increase in both strength and toughness, and brings about a reduction in the time of vulcanisation to 4 hours. The ½% and 1% mixings show a very decided improvement in tensile properties. The toughness of each mixing increases with the addition of D.P.G., and in both cases flat curing properties are beginning to be evident. The strength attained by the last of the 3% sulphur series is noteworthy when considered alone, and is outstanding when contrasted with that of the control.

The same features may be noticed by referring to the tensile figures for the 5% and 7½% sulphur mixings. The various effects, however, are becoming very much intensified with increase in the quantity of sulphur. The only exception to this is that in the case of the two mixings containing only ⅛% of accelerator, the tensile strength is less than that of the control. The 7½% sulphur mixing with 1% of D.P.G. gives a strength of 2·13 kg. per sq. mm.

The 10% and 15% sulphur mixings represent a retrogression. They do not reach the same strength or toughness as the previous mixing, although there is a slight increase in acceleration. Reduction in strength with the addition of small quantities of D.P.G. is again noticeable. In spite of the retrograde movement with respect to tensile properties, both series of mixings are still satisfactory as regards strength, especially those containing larger quantities of accelerator.

In order to demonstrate the general features of D.P.G. as an accelerator, and to indicate clearly the type of mixing in which it should be used, a series of diagrams have been made. Fig. 1 shows how the maximum load obtained over the range of cures

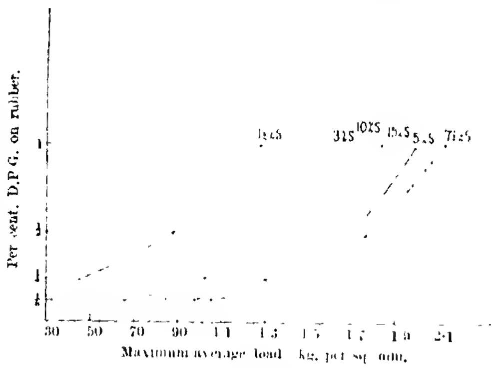

FIG. 1.

behaves with different quantities of accelerator in mixings containing different quantities of sulphur. After the points on this diagram had been plotted, it was found that they lay on a series of curves which corresponded to the different proportions of sulphur. This is the case, also, for the other diagrams, except for Fig. 4, which is an indication that the quantity of sulphur present is one of the main factors determining the properties of an accelerated mixing. Reverting to Fig. 1, it is clear that for every mixing, increase in the quantity of D.P.G. produces an increase in strength, the increment being greater when the quantity of accelerator present is small than when it is already large. As sulphur is added up to 7½%, the curves move further away from the D.P.G. axis and do not intersect, showing that the breaking load becomes greater as the proportion of sulphur is increased, no matter what quantity of accelerator is present. The 10% and 15% curves

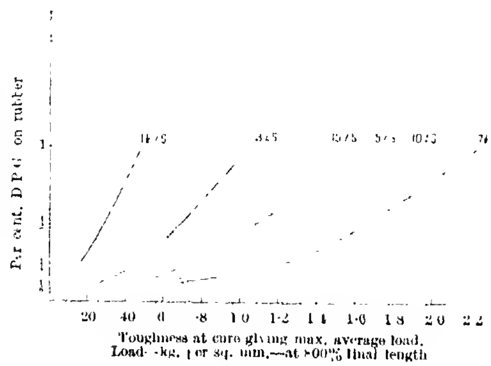

FIG. 2.

lie, however, nearer the vertical axis, which indicates that for all quantities of D.P.G., adding sulphur beyond 7½% causes the strength to decrease. This result cannot be due to the addition of sulphur alone, for a 10% sulphur mixing containing no accelerator possesses a better tensile strength than

one containing 7½%; it must therefore be due to the sulphur and D.P.G. together.

Fig. 2 shows the relation between the toughness (measured by the load required to produce a final length of 800%) of the mixings when they are at their maximum strength, and the quantity of accelerator present, for the different proportions of sulphur. This is thus a comparison of the toughness of the mixings under similar conditions of cure. As noted above, points when plotted lie on curves corresponding to the proportion of sulphur in the mixing. Further, however, for small quantities of sulphur the curves are straight lines, showing that the additional toughness due to the accelerator is practically proportional to the quantity of D.P.G. present. For all the curves the toughening effect increases with the addition of accelerator. When the amount of sulphur present is large, the increase is greatest when the proportion of D.P.G. is small. As regards their position relative to the D.P.G. axis, the curves on Fig. 2 are similar to those on Fig. 1, the toughening effect increasing for all quantities of D.P.G. up to 7½% sulphur and diminishing for quantities of sulphur greater than that. Toughness and strength thus vary similarly in mixings accelerated with D.P.G.

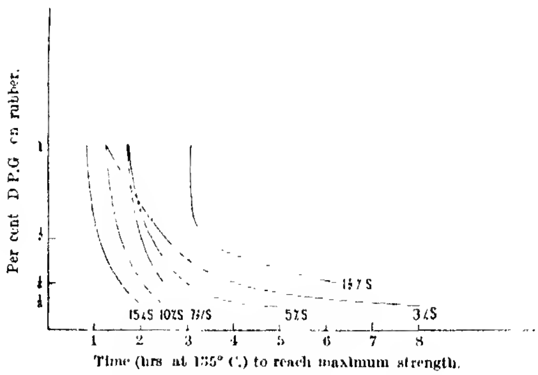

FIG. 3.

Fig. 3 shows the time (at 135° C.) required to reach the maximum strength, plotted against quantity of accelerator. Again, curves for the different proportions of sulphur can be drawn. Their position with respect to the D.P.G. axis indicates that as the quantity of sulphur is augmented, the time of cure is reduced, and there is no break in the continuity of this law at the 7½% curve. From 1½% to 15% sulphur the curves gradually approach the vertical axis. The portions of the curves above the ½% line are practically parallel to the D.P.G. axis, indicating that there is almost no increase in acceleration when more than ½% of D.P.G. is added. The acceleration is produced greatest with small quantities of sulphur, and the lower part of the curves being almost parallel to the time axis, the maximum increase in acceleration is obtained with proportions of accelerator less than ½%. The slope of the lower part of the curves gradually diminishes as sulphur is added, so that for large proportions of sulphur a small quantity of D.P.G. is almost as effective in reducing the time of cure as a large quantity.

An attempt has been made in Fig. 4 to show that when use is made of an accelerator, certain limitations are imposed in order that the good qualities imparted by such a material may be utilised to their fullest extent. The three properties which are most likely to require consideration in producing a new mixing are time of vulcanisation, strength, and toughness. Fig. 4 shows maximum strength plotted against the

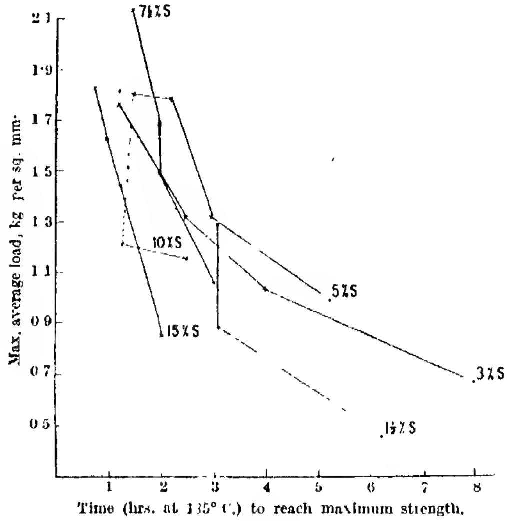

FIG. 4.

time (at 135° C.) required for its development. A similar diagram could be drawn for toughness. For convenience in identification purposes points representing mixings containing the same quantity of sulphur have been connected up. It will be observed that the majority of the mixings reach their best strength between 1 hour and 3 hours at 135° C. A few of very low strength take longer. This indicates that if a mixing is to be produced containing D.P.G. possessing good tensile properties, other circumstances must be such that it can be heated for about 1 hour at 135° C. subject to the influence of the compounding ingredients used. A similar diagram for toughness is not shown here, but it should be noted that satisfactory mixings containing D.P.G. will have certain definite limits of toughness between which they will lie, again subject to the effect of other ingredients. This is very important technically, as it indicates that radical alterations may have to be made in the compounding ingredients of a technical mixing when this accelerator is added in order that the accelerated mixing may possess exactly similar properties to the original, or conform to some specification. In some cases it is conceivable that the use of D.P.G. may be impossible.

Hitherto, in discussing the results, it has been assumed that the time taken to reach the maximum strength indicated when the mixings were fully

vulcanised. In Table IV. are given times of vulcanisation which are considered suitable for technical work, together with the strength developed.

TABLE IV.

15	¼	2	0·85
	½	1½	1·41
	¾	¾	1·15
	1	½	1·30

These have been arrived at by taking the first cure giving a reasonably good strength. In most cases the maximum strength is not reached until the mixing has been heated for a considerably longer period, and in all instances except for a few mixings containing a small quantity of sulphur or a small quantity of accelerator, there is a long range of time over which good tensile properties may be obtained. For technical work, therefore, most of the above mixings possess a very big margin of safety. Reference to Table III. shows that this accelerator produces mixings which are very much flatter curing than the controls. This must be reckoned as one of the most valuable properties of D.P.G.

From the above investigation it may be concluded that the best type of mixing to use with this accelerator is one in which the quantity of sulphur is in the neighbourhood of 7½% of the rubber, and the accelerator approximately ½% of the rubber. The quantity of sulphur necessary to bring out the full effect of D.P.G. is thus rather in excess of what might have been expected.

Hitherto, this work has dealt with mixings which are practically pure, containing only sufficient zinc oxide to activate the D.P.G. The possibility arises, however, that the conclusions may not be valid for compounded mixings particularly when active ingredients are present. As it is certain that the presence of active fillers does not invalidate the previous results, inactive fillers will not, it is sufficient to investigate how D.P.G. behaves in mixings containing large quantities of zinc oxide and light magnesium carbonate. Litharge is not considered, as it is such a good accelerator by itself, that it does not appear necessary or advisable that it should be used along with a powerful organic accelerator. Accordingly, the next portion of the experimental work dealt with mixings containing large quantities of zinc oxide and of light magnesium carbonate. In order to reduce the work necessary to a manageable amount, four representative mixings were chosen in such a way that the conclusions from their behaviour would be general for any combination of accelerator and sulphur. Two of the mixings contained a large quantity of sulphur with large and small quantities of D.P.G. respectively. The other two mixings contained a small quantity of sulphur with large and small quantities of D.P.G. respectively. Again, instead of adding different amounts of filler to these control mixings, the largest quantity of zinc oxide and of magnesia which can be efficiently used in rubber, was fixed upon as a suitable quantity to investigate. This procedure is justifiable in that addition of these substances up to that amount causes a progressive change in the physical characteristics of the rubber, and maximum effects were therefore being investigated. The actual quantity of filler which was added, namely 30% of zinc oxide, and 15% of light magnesium carbonate, had already been determined in previous experiments, and is in accordance with that indicated by Wiegand (India Rubber J., 1920, 60, 423).

Each mixing was cured over a range so as to exhibit the maximum tensile properties, and ring test pieces from each heat were tested on the Schopper machine. The resulting tensile figures are shown in Table V. For convenience the tensile figures for the controls have been abstracted from Table III., and are shown alongside those of the corresponding zinc and magnesia mixings. The figures given in the table are again average values obtained by breaking three rings.

With mixings containing a large quantity of sulphur and 1% of accelerator, the addition of zinc oxide causes a reduction in strength, and also probably slows down the rate of vulcanisation. It produces, however, a slightly tougher rubber, this effect being

rather more marked at an advanced state of cure. The addition of magnesia to the mixing decidedly improves its qualities. Increased strength is obtained from a rubber already outstanding in this respect, coupled with a considerable increase in toughness, rendering the magnesia mixing superior to the zinc mixing. The addition of magnesia also appears to produce further acceleration in the rate of vulcanisation.

Similar effects are noticeable with mixings containing a large quantity of sulphur and a small quantity of D.P.G. The control mixing in this instance—not a particularly good one in respect of tensile properties—is not improved by the addition of zinc oxide. The strength shows a distinct tendency to drop. The maximum strength is not attained until 4½ hrs., as against 3 hrs. for the control. The only improvement effected by the addition is a slight increase in toughness. Very different is the action of the magnesia. The strength is very much increased, and the rate of cure of the control not only maintained, but probably slightly increased. Again, there is a great increase in toughness. Perhaps the most remarkable feature of this magnesia mixing is its flat-curing property. The strength remains good from 2½ to 4½ hrs., and though the mixing is gradually increasing in toughness the increase is not great. The other magnesia mixing possessed the same flat-curing properties as regards strength, but not as regards toughness.

The mixings containing a small quantity of sulphur with a large quantity of accelerator show the effects due to the addition of the two fillers better than any others. The addition of zinc oxide in this case produces practically no alteration in strength, and there is a slight increase in toughness. The rate of cure, however, is slowed down very considerably, the increase in the time required to reach the maximum strength being 1¼ hrs. on an original heat of 1¼ hrs., or 100%. The zinc oxide mixing shows rather a long range of cures which give good strength. The action of the magnesia is very marked. There is an increase in strength, coupled with a slight increase in the rate of cure. A very great toughening effect is produced. In respect of strength the mixing is very flat curing. In general qualities this magnesia mixing is very much superior to the corresponding zinc one.

The last lot of mixings containing a small quantity of sulphur along with a small quantity of D.P.G. is very disappointing. The control in this instance has poor tensile properties, and the addition of fillers does not improve matters. Both zinc oxide and magnesia seem to slow down the rate of vulcanisation of the already slow-curing control.

Considering these results generally, it is evident that the effects produced by the addition of zinc oxide to a mixing accelerated with D.P.G. are not very desirable. Firstly, no increase in strength is produced, there being in fact a slight diminution, which, however, is negligible, particularly as the accelerated mixings are usually very strong. The toughening effect is less than would have been expected. That is, the zinc oxide has a smaller effect on the accelerated mixing—which has already been toughened—than it has when no accelerator is present. The magnitude of the toughness induced by zinc oxide varies with different types of mixings, increasing as the sulphur decreases or with decrease in the quantity of accelerator. It is a well-known fact that the addition of an active filler to a mixing already containing another active filler produces less increase in toughness than if the second filler had been added to a pure stock. In the case under consideration, sulphur and accelerator behave as if they were equivalent to an active filler, so that the full benefit of the toughening powers of the zinc oxide is not obtained. Another disadvantage of using D.P.G. in zinc oxide mixings is the reduction in the rate of cure produced by so doing. This retarding effect of the zinc oxide is greatest when the quantities of accelerator and sulphur present are small. It can be shown that zinc oxide alone has no effect on the time of cure as measured by the time taken to reach maximum strength, so that the retardation noted above must be due to the zinc oxide and D.P.G. conjointly. It is, in fact, a reversal of the activation process. The activity of D.P.G. must be brought up to a maximum by the addition of zinc oxide and then slowly reduced. The magnitude of such an effect would obviously be influenced by the amount of sulphur and accelerator present, and, in particular, it would be greater with small amounts of accelerator. From the behaviour of the mixings investigated, it is concluded that D.P.G. should not be used in zinc oxide mixings unless it is permissible to have present as much as 1% of D.P.G. on the rubber along with a fairly high sulphur content.

The general effects of the addition of light magnesium carbonate to D.P.G. mixings are very different. For all mixings except when accelerator and sulphur are both present in small quantities, the addition of magnesia produces an increase in strength, an increase in the rate of cure, and a toughening effect very similar to what would be obtained if no accelerator had originally been present. The increased strength is most marked when a small quantity of accelerator is used along with a large quantity of sulphur. The augmented toughness is perhaps most marked with a small quantity of sulphur and a large quantity of accelerator. Although it fails to effect any improvement in mixings where both the sulphur and accelerator content are low, the mixings examined above are sufficient to show that in magnesia mixings the good properties of this accelerator are exhibited to their fullest degree.

Hitherto, nothing has been encountered which would indicate that as an accelerator D.P.G. behaves any less efficiently in compounded mixings than in mixings containing nothing but rubber, sulphur, and sufficient zinc oxide to activate it. However, in making experiments with accelerated mixings containing brown rubber substitute, considerable trouble was experienced due to porosity. It has since been noted (Lefebure, India Rubber J., 1923, 66, 932) that D.P.G. does not give good results with mixings containing white substitute. To investigate this

matter, a control (113½ pts.) consisting of hard fine Para 100, zinc oxide 5, sulphur 7½, and D.P.G. 1, was tested alone and with increasing quantities of brown substitute as shown in Table VI. The control and the first four mixings were heated in an autoclave press in the form of slabs for ¾ hr. at 135° C. The last mixing was heated in the same way for 1 hr. at 142° C. In none of the samples could any signs of porosity be detected.

* With additional 9% of light magnesium carbonate

As might have been expected, with increase in the quantity of substitute the strength diminishes. The mixings also become rapidly softer, and that may be taken as an indication of the rate of cure being slowed down as the substitute is increased. Magnesia was added to the last mixing in the hope that it would effect an improvement. The reverse is the case. The porosity encountered in mixings of this type is probably due to the slowing down of the rate of cure. From these results it would appear that D.P.G. should not be used along with mixings containing brown substitute. Although figures are not given, the same conclusion applies to white substitute. Probably the reason for this incompatibility of substitutes and accelerator is to be found in the traces of acid always present in these materials.

Another factor which requires consideration when an accelerator is added to a mixing is its influence, if any, upon the ageing properties of the rubber. There has, perhaps, always been some suspicion that rubber containing accelerators is liable to perish more rapidly than ordinary mixings. This point was investigated for D.P.G. by subjecting two of the mixings to an artificial ageing test in an oven. As there is a general similarity in behaviour amongst the mixings dealt with, the choice of two, as being sufficient to indicate the ageing qualities of D.P.G. mixings in general, seems legitimate. The mixings chosen contained large and small quantities of sulphur respectively, with enough D.P.G. in each case to ensure that the mixings would possess reasonably good strength when properly cured, and would also be fairly fast curing. Both mixings contained hard fine Para 100, and zinc oxide 5, whilst A contained in addition 7½ pts. of sulphur and ½ of D.P.G., and B 3 of sulphur 1 of D.P.G. Large batches of A and B were mixed, and sufficient of both vulcanised to provide 55 rings for testing on the Schopper machine. Each mixing was vulcanised for two different times, one of which was supposed to be below that giving the optimum tensile figures, while the other was supposed to be that giving the maximum strength. However, the heats for A turned out to be rather long, and both are actually over-cures. In order to eliminate errors in vulcanisation, as many slabs of each mixing were heated together as practical difficulties would allow. After curing, five rings of each heat were tested, and the remainder of the slabs put into a ventilated oven which was automatically kept at a temperature of 70° C. Each day after this slabs were removed, allowed to cool, and tested. Tensile figures for every second day are shown in Table VII., readings representing averages being obtained by breaking 5 rings.

With mixing A the loads obtained for both cures gradually diminish from the start, which shows that it has been over-cured. In spite of this the load shows no sudden decrease until the 10th day. This is better than the usual behaviour of rubber-sulphur mixings. The strength remains quite noteworthy for 6 days. As the rubber ages there is a gradual increase in toughness, but not as much as might have been expected. The longer cure represents a rather bad over-cure, and the strength breaks down after two days, as an unaccelerated mixing would do under similar circumstances. Considering that the short cure is an over-cure, mixing A possesses very good ageing properties.

Mixing B appears to be very outstanding in ageing qualities. In the case of the short cure the load slowly rises to a maximum which is reached in 5 days, and then gradually diminishes. The long cure reaches its maximum in two days. Both heats must, therefore, have been under-cures, although the longer heat is practically a correct cure. In neither case is there much increase in toughness, nor does either heat show signs of breaking up after 10 days in the oven. The strength of the longer heat is still at 1·41 kg per sq mm. after 10 days, which is quite outstanding.

TABLE VII.

Age in days	Load. kg mm².	Final length %	Toughness 700% load, kg mm²	Load kg mm²	Final length. %	Toughness 700% load, kg mm².
Mixing A.	Cure 1¼ hr at 135° C			Cure 1¾ hr. at 135° C		
0	1·83	879	0·66	1·30	777	0·86
2	1·70	884	0·61	0·52	574	0·81
4	1·56	834	0·73	1·00	639	0·98
6	1·39	806	0·71	0·23	436	
8	1·14	717	0·70	0·08	374	
10	0·48	578	0·71	0·16	340	—
Mixing B	Cure ¾ hr at 135° C			Cure 1¼ hr at 135° C		
0	1·55	945	0·40	1·66	903	0·51
2	1·53	952	0·40	1·70	910	0·54
4	1·65	936	0·42	1·41	845	0·66
6	1·68	939	0·42	1·44	854	0·65
8	1·57	944	0·41	1·45	850	0·64
10	1·34	953	0·32	1·41	856	0·62

From this it is evident that D.P.G. mixings show good ageing qualities when subjected to artificial ageing. On the whole, it is probable that mixings containing a small quantity of sulphur age better than those containing a large quantity, but there appears to be not the least danger in using a large quantity. The smallness of the increase in toughness as D.P.G. mixings age may prove a valuable property.

Besides the possibility of the use of an accelerator spoiling the ageing properties of rubber, another contingency which has to be guarded against is the possibility of the accelerator being sufficiently active to cause premature vulcanisation while mixing operations are being carried out, or during subsequent calendering or extruding of the mixing. This phenomenon is one which does not lend itself very

readily to strictly accurate investigation. However, an attempt has been made to deal with the problem in the following way. The mixing chosen contained rubber 100, zinc oxide 5, sulphur $7\frac{1}{2}$, and D.P.G. 1%, and was one of the fastest curing D.P.G. mixings obtainable. Small portions of the mixing were put into a mould similar to those used for the oil-bath method of heating (Comm Netherlands Govt. Inst., 1917, 139). After clamping up, this mould was placed in a water-bath which could be kept at any desired temperature up to boiling point, and allowed to remain for 5 hours. Samples were heated at 70°, 78°, 88°, 93°, and 97° C. After heating, each sample was carefully examined for signs of curing, a good test being to note the behaviour on passing through a hot mill. The samples heated at 70° and 78° showed no signs of vulcanisation. That heated at 88° was just set. In the case of the 93° and 97° samples, there was no doubt that some vulcanisation had taken place. The critical temperature of this accelerator is, therefore, somewhere about 88° C. That is to say, below that temperature there is either no vulcanisation, or the process is so slow as to escape detection. There is, however, another factor to be considered in connexion with premature vulcanisation, that is the rapidity with which the acceleration increases as the temperature rises above the critical value. The actual investigation of this at low temperatures would be laborious if not impossible, but from the known acceleration at 135° C. it appears that the acceleration will not increase sufficiently rapidly round about 100° to render premature vulcanisation a danger. This becomes more evident when the actual temperature reached on a mixing mill is considered. The temperature of several batches was taken immediately after removal from the mixing mill. As these batches were from 50 to 100 lb. in weight, and were in the form of compact rolls, the temperature of the centre of a roll will be a good indication of the temperature reached on a mixing mill. This was observed for a variety of technical mixings and found to vary from 81° to 85°, which is below the critical temperature for D.P.G. There should, therefore, be little danger of premature vulcanisation in the case of D.P.G. mixings, particularly when it is remembered they will only be at that temperature for a short time.

In considering the milling and mixing of accelerated mixings, another interesting point arises. It is well known that a number of organic accelerators have a marked depolymerising effect on rubber, and therefore they may be used to reduce the time of grinding necessary before solid materials can be incorporated. D.P.G. possess this property in no inconsiderable degree, as will be seen by the following experiment.

A batch of rubber was ground for 20 minutes and 1% D.P.G. added during the last two or three minutes. Another similar batch was ground for the same length of time, but the 1% D.P.G. was added at the start. When solution viscosities of the two rubbers had been determined by means of the Ostwald viscosimeter it was found that the first batch gave a viscosity number approximately twice that of the second batch. This indicates that by the addition of D.P.G. to rubber before grinding or at the start of grinding, less time will be required to reduce the rubber to a certain degree of plasticity than if no accelerator had been present.

Summary.

The conclusions reached in this paper may be summarised as follows :—

(1) Diphenylguanidine possesses accelerating powers of the same order as *p*-nitrosodimethylaniline.

(2) Diphenylguanidine improves the strength and toughness of mixings and imparts flat-curing properties.

(3) The optimum quantities of diphenylguanidine and sulphur are $\frac{1}{2}$ to $\frac{3}{4}$% of the former, and 5 to 7% of the latter.

(4) This accelerator gives similar results with mixings compounded with zinc oxide and light magnesium carbonate. It is more satisfactory, however, with large quantities of magnesia than with zinc oxide.

(5) Brown and white substitutes appear to h[illegible] retarding effect, and such mixings do not [illegible] good results.

(6) Diphenylguanidine mixings possess exc[illegible] ageing qualities when subjected to a[illegible] ageing tests, particularly if the sulphur is low.

(7) There appears to be little danger of pr[illegible] vulcanisation when this substance is pr[illegible] mixings.

(8) Diphenylguanidine possesses the property of softening rubber.

In conclusion, the author has to acknowledge his indebtedness to the management of the North British Rubber Co., in whose laboratories the above investigation was carried out, for permission to publish this paper.

Castle Mills, Edinburgh.

THE DISTRIBUTION OF THEOBROMINE DURING THE FERMENTATION OF CACAO.*

BY A. W. KNAPP AND R. V. WADSWORTH.

One of the effects of the fermentation of cacao is stated by Van Hall in his well-known book to be "the liberation of the theobromine, the substance which gives cocoa its peculiar tonic and stimulating properties."

Hilger and Lazarus[1] have shown the presence of a glucoside, Schweitzer[2] calls it "cacaonin"; which he gives its formula as $C_{60}H_{86}O_{15}N_4$, and affirms that by the action of an enzyme it is decomposed into theobromine, dextrose, and cacao-red. This Sack[3] expresses in the following equation :—

$$\underset{\text{Cacaonin}}{C_{60}H_{86}O_{15}N_4} + 8H_2O + 25O = \underset{\text{Theobromine}}{C_7H_8O_2N_4} + \underset{\text{Dextrose}}{6C_6H_{12}O_6} + \underset{\text{Cacao-red}}{C_{17}H_{12}(OH)_{10}}$$

*Read at a meeting of the Birmingham Sect on on March 18, 1924.
[1] Hilger, Apoth.-Ztg., 1892, 469.
[1] Lazarus, Botanisches Centr., 1893, 41, 296.
[2] Pharm. Ztg., 1898, 42, 389.
[3] Sack, J. Bull. No. 10, 1908, Dept. of Agriculture, Surinam.

On the other hand, A. Goris and G. Fluteaux[4], Ultée and van Dorssen,[9] failed to find cacaonin, or any analogous substance.

The above equation is difficult to accept for many reasons. If all the theobromine in unfermented Forastero cacao existed as cacaonin there must be at least 10·5% of the glucoside present, and considering that 50% of the bean consists of fat, it should be a very obvious constituent of the bean. Further, during drying the brown colour (?cacao-red) of the bean continues to develop, but the fermented bean does not contain any more reducing sugars than the unfermented bean. Whilst in the opinion of the present authors the presence of cacaonin requires further confirmation, it is admitted that there may be present in the unfermented bean a compound of theobromine and tannin[5], but if there is, it must be very easy to decompose. For example, a weak alkali like magnesia must completely decompose it.

Fermented and unfermented beans were finely [illegible]d. Part of each of these was heated for one [illegible] with 5% sulphuric acid. The theobromine being [illegible]en determined by the Dekker process, in which Magn[illegible]sia is used.

Theobromine by Dekker process.

	Original sample.		After hydrolysis.
[illegible], unfermented ..	1·58%	..	1·32%
[illegible], fermented ..	1·15%	..	1·03%

[illegible] results suggest that, allowing for the error [illegible] may occur in the Dekker process, if a glucoside or hydrolysable compound is present, the magnesium oxide is a sufficiently strong alkali to decompose it completely.

An attempt was made to settle this question of the presence of a glucoside by using Maupy's method of determination of the theobromine, because this method depends on its solubility in phenol-chloroform, without either acid or alkaline treatment. By this method 1·45% of theobromine was obtained from the fermented beans, and 1·35% from the unfermented. Even if it had not been evident that the theobromine from the fermented beans was the more contaminated with colouring matters etc., 0·1% would be a small amount of theobromine to have been liberated by fermentation. It was also attempted to extract the theobromine direct from the dry material by means of chloroform. The extract was washed with light petroleum to remove the fat, and the theobromine dissolved in water to separate it from insoluble material; 0·96% was obtained from the fermented, and 0·79% from the unfermented cacao. This result must be accepted with caution, as it is obvious that in neither case was the whole of the theobromine extracted. Finally the most accurate method of determination known to the authors[6] was tested on ground cacao nib from which the fat had been extracted. Part of this material was first treated with 10% hydrochloric acid for four hours at 95° C. The results obtained show that the acid treatment caused not the slightest increase in the amount of theobromine found.

[6] Wadsworth, R. V., Analyst, 1921, 46, 32.

Cacao		Theobromine in dry fat-free nib. Without acid treatment.		With acid treatment.
Well fermented Jamaica	..	2·48%	..	2·44%
Lightly fermented Arriba	..	2·98%	..	3·00%
Totally unfermented Accra	..	3·80%	..	3·76%

On treating the residues from this method by other processes, no further theobromine has been obtained.

Instead of an increase in theobromine in fermented cacao, it has invariably been found in cacaos of the same kind that the fermented samples contain less theobromine than the unfermented. From our knowledge of the fermentation of cacao this is what would have been expected. The bean becomes full of an acid liquid during the fermentation, which results in some of the theobromine going into solution. A very little might thus escape in the "sweatings," *i.e.*, the juice which runs away. On drying the juicy bean, theobromine would tend to be concentrated on the outside, that is the shell, where the evaporation is taking place. Actually it is found that the shell of the bean fresh from the pod contains only a trace of theobromine, and it is probable that any theobromine found therein comes from the cotyledons, so that the cacao nib naturally contains less theobromine after fermentation. In order to determine accurately the distribution of the theobromine that occurs during fermentation, the authors arranged with Mr. Stanhope Lovell in Trinidad to supply samples of the same mixture of beans after various periods of fermentation. Amongst other analytical figures on these samples, the theobromine and the total nitrogen were determined.

Trinidad cacao (mainly Forastero).

Fermented	Shell (on dry shell).		Nib (on dry fat-free nib)					
	Theobromine	Gain	Theobromine.	Loss	N in theobromine	Loss	Total N.	Loss
Days	%		%		%		%	
0	0·28		2·96	—	0·92	—	5·28	—
2	0·28	—	3·05	—	0·95	—	5·39	—
4	2·35	2·07	2·57	0·43	0·80	0·11	5·05	0·29
6	2·35	2·07	2·36	0·64	0·73	0·20	4·97	0·37
8	2·33	2·05	2·23	0·77	0·69	0·24	4·84	0·50
10	2·23	1·95	2·22	0·78	0·69	0·24	4·71	0·63

The mean of the figures for 0 and 2 days is taken as a basis from which to calculate the loss or gain. The total nitrogen was determined by the Kjeldahl process.

In the above fermentation it is evident that at some period greater than two and less than four days, the distribution of the theobromine took place. From our experience this would be expected to commence somewhere about the sixtieth hour, that is, when the temperature has risen high enough to kill the bean, and the acid liquid has commenced to diffuse freely through the cotyledons. The distribution of theobromine appears to start at a fairly definite period, and an appreciable percentage of the theobromine appears to go almost immediately into solution. There is reason to believe that the theobromine found in shell after fermentation really exists as such, as it is completely removed from the dry shell by anhydrous solvents, such as chloroform. The theobromine in the nib cannot be completely extracted under these conditions, which may be because the solvent does not readily penetrate the cell wall, and

a certain observation points either to this, or to the presence of a very easily decomposable compound. It has been found to be impossible by any method to extract completely the theobromine from cacao nib, save in the presence of water. This corresponds to the observation of Gorter[7] concerning the caffeine in coffee, and certainly suggests either the presence of a compound which is decomposed by water, or that the cell walls are pervious to water but not to solvents like chloroform.

An attempt was made to balance the losses and gains of theobromine; thus after four days' fermentation:—

85·2 parts of nib lost 0·43% theobromine=0·36 pt.
14·8 parts of shell gained 2·07% theobromine =0·31 pt

This is a good agreement, but for longer periods the loss exceeds the gain appreciably. The "sweatings" contain about 0·03% of theobromine, and as roughly 100 lb of dry beans give 10—20 lb. of "sweatings," loss of theobromine from the beans in the "sweatings" might account for the difference in the figures obtained after four days' fermentation. After four days there are no "sweatings" running away, and if the theobromine has not been rubbed off the shell, it can only be suggested that it has been lost by decomposition. Other nitrogenous substances besides theobromine are lost in comparatively large quantities as the fermentation proceeds. It may be pointed out here that it is not usual in Trinidad to ferment for so long a period as ten days.

An attempt to find out more definitely just when the theobromine first went into the shell showed that it began within 24 hours, but there was a sudden increase between 48 and 60 hours.

Period of fermentation—Trinidad beans	½	1	1½	2	2½	3	3½	4	4½ days.
Theobromine in dry shell (%)	0·24	0·37	0·44	0·72	1·28	1·30	1·45	1·68	1·53

By the kindness of a cacao planter the authors were able to repeat the Trinidad experiments in Ceylon on Forastero cacao, and a large number of analyses were made. As the object of the methods as followed in this case was merely to remove th pulp and give the shell a beautiful appearance, an the total period of fermentation did not excee 36 hours, the temperature never rose high enough t produce those changes in the interior of the bea which are usually associated with fermentation Hence there is very little change in the theobromine content of the beans, or of the shell.

Period of fermentation.	Theobromine. In dry nib. %	Theobromine. In dry shell. %
0 days	1·52	0·03
,, (washed)	1·61	0·03
½ day	1·54	0·20
,, (washed)	1·53	0·17
1 day	1·58	0·18
,, (washed)	1·50	0·18
1½ days	1·53	0·46
,, (washed)	1·44	0·37

The washing of the beans did not appear to affect appreciably the theobromine content of shell or nib, a conclusion which in the case of cacao shell is contrary to the expectation expressed by one of us in a previous paper.[8]

Conclusion.—The figures which are included in this paper definitely prove a suggestion originally made by one of the authors[8] from an examination of the cacao beans of commerce, that theobromine passes into the shell during fermentation.

Theobromine, free and combined, exists only in the cotyledons of the fresh cacao bean. The skin of the fresh bean is practically free from theobromine As fermentation proceeds the temperature rises high enough to kill the bean, and at once the liquid which permeates the bean contains theobromine. Thus theobromine passes into the shell, so that it is usual in a well-fermented bean of the Forastero type to find from 0·8 to 2·98% of theobromine in the dry shell, practically all of which has come from the cotyledons. Hence the longer the fermentation, the less theobromine will be found in cacao "nibs."

The authors wish to thank Messrs. Cadbury Brothers, Ltd., for permission to publish this paper, the whole of the analytical work for which was done in their Research Laboratory at Bournville.

THE CORROSION OF COPPER AND COPPER ALLOYS.

BY ULICK R. EVANS.

It has been pointed out in previous papers[1] that the corrosion of metals like zinc, iron, and lead is caused by electric currents set up through unequal access of oxygen to different parts of the surface; the attack tends to become concentrated at any part of the surface which happens to be relatively inaccessible to oxygen, since that part will form the anode of the cell. It is true that the accumulation of metallic salts at the anodic area may sometimes tend to diminish slightly the strength of the current after a time; but, unless the primary anodic corrosion-product is insoluble, the current will not usually drop to zero. In the corrosion of a noble metal such as copper, the E.M.F. set up through "differential aeration" will always be small, and, if copper salts accumulate to any extent at the anodic places, current may finally cease to flow; in that case, corrosion will come to an end.

The essential difference between the behaviour of copper and that of the more reactive metals is shown by the following simple experiment. If two electrodes of iron are placed in a divided cell containing potassium or sodium chloride solution in each compartment, and if air, free from carbon dioxide, is bubbled through one compartment, a current is produced, the aerated electrode being the positive pole; the same effect is obtained if the electrodes consist of zinc, cadmium, or lead. If, however, the experiment is repeated, using copper electrodes, the current produced flows in the opposite direction, unless special precautions are taken to eliminate oxygen from the side over which no bubbles are passing; if a certain amount of oxygen is present on both sides, the pole over which bubbles are made to pass becomes the negative pole. Investigations have shown that this abnormal current is not the effect of aeration, but of stirring. If the liquid in one compartment has previously been rendered moderately free from oxygen by heating, and if it is covered with a layer of paraffin to prevent access of the gas, then when air is bubbled through the other compartment, the electrode in the "aerated" compartment becomes the positive pole, notwithstanding the stirring which is produced. Thus, under appropriate conditions, copper obeys the same law as the other metals.

If, on the other hand, dissolved oxygen is present in both compartments, and one side is stirred mechanically, the electrode on that side immediately becomes negative, owing to the removal of copper ions from the surface of that electrode, with the production of a concentration cell. In fact, the cell

Copper | Potassium chloride solution (stirred) | Potassium chloride solution (stagnant) | Copper

is precisely analogous to the cell

Copper | Potassium cyanide solution | Potassium chloride solution. | Copper

In both cells the copper on the left-hand side acts as negative pole (anode), owing to the smaller concentration of copper cations around it; in the second case the copper cations are removed through chemical destruction by the cyanide, whilst in the first case they are removed mechanically by the stirring.

The practical consequences of the difference in the behaviour of copper and iron are important. Imagine an iron article immersed in a stream of running water. The corrosion is likely to be concentrated at the recesses or crannies in the surface, since these are the parts least accessible to oxygen; as the total area suffering corrosion is small, the linear rate of penetration downwards will be comparatively large. If, on the other hand, the article is of copper, corrosion is unlikely to occur at these comparatively stagnant places, unless they are kept completely free from oxygen (*e.g.*, if they are shielded by a layer of a substance like cuprous chloride, which absorbs oxygen); otherwise the attack is likely to be distributed over the whole surface of the article—a much more desirable state of affairs. Where, however, there exist certain limited areas from which the copper salts are likely to be removed more quickly than from other points, these points may be expected to be anodic and to suffer specially rapid corrosion; as will be shown, this local removal may take place in more than one way.

Thus localised corrosion of copper and copper alloys may be set up: (*a*) through the preferential removal of copper salts from certain areas; (*b*) through the shielding of certain areas from aeration, giving a "differential aeration cell" similar to those operative in zinc and iron. These causes have been investigated by means of observations conducted upon copper and various kinds of brass; the experiments specifically described below were carried out with electrolytic copper, and a brass containing 63·80% of copper, which was practically free from lead. The metals were cleaned with emery immediately before the experiments.

(*A*) *Localised corrosion caused through preferential removal of copper salts from certain areas.*

(1) *Corrosion due to inequalities in the velocity of the liquid.*—An example of localised corrosion has recently been observed in the copper tube of the central condenser installed at the Cambridge University Chemical Laboratory for the production of distilled water. The condenser, which is of the form shown in Fig. 1, was furnished with a pinched copper tube, originally tinned externally; the steam passed

[1] U. R. Evans, J. Inst. Metals, 1923, **30**, 239; J. Oil & Colour Chem. Assoc., 1923, **6**, 150. Proc. Camb. Phil. Soc., 1924, **22**, 54; Chem. and Ind., 1924, **43**, 222.

through the tube, and cooling water drawn from the town water supply passed outside it. After some years the tube failed, and on inspection it was found that a very deeply corroded area, with actual perforation at one point, had appeared near the bottom, at the level where the cooling-water was introduced.

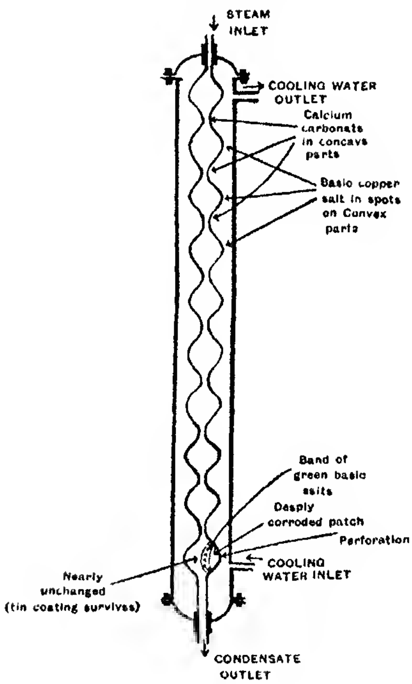

FIG. 1.

This was confined to one side of the tube (presumably that opposite the inlet pipe); the corroded area was surrounded by a deep green adherent deposit, mainly basic copper carbonate, with some chloride. The lower part of the tube was remarkably free from scale, but in the upper part, an adherent scale of calcium carbonate had been produced at the concave portions of the tube; the convex projections were free from scale, and were covered with spots of the green corrosion-product.

The production of the scale of calcium carbonate indicates that alkali must have been produced at the concave portions in the upper part of the tube, and suggests that these places were cathodic; it is noteworthy that these are just the places where the velocity of the water must have been least. On the level of the entry pipe, where the velocity of the water was certainly greatest, the copper was evidently anodic, and suffered serious local corrosion. The green basic salt was presumably produced where the anodic product (copper salts), and the cathodic product (alkali) met and interacted. It is unfortunate that absence of information regarding the original annealing of the tubes, and uncertainties introduced by the fact that the tube was originally covered with tin (which covering survived intact over a large part of the surface of the lower part of the tube, on the opposite side to the corroded patch) make it impossible to say that this is the only factor involved; but the description given almost certainly conveys a truthful account of the essential mechanism of the process.

(2) *Water-line attack in dilute acids.*[1]—The local removal of copper salts from certain points may also be produced by gravity or by capillary forces. The well-known water-line attack, which is so characteristic of copper and its alloys, affords an interesting example. If a sheet of copper (Fig. 2) is half

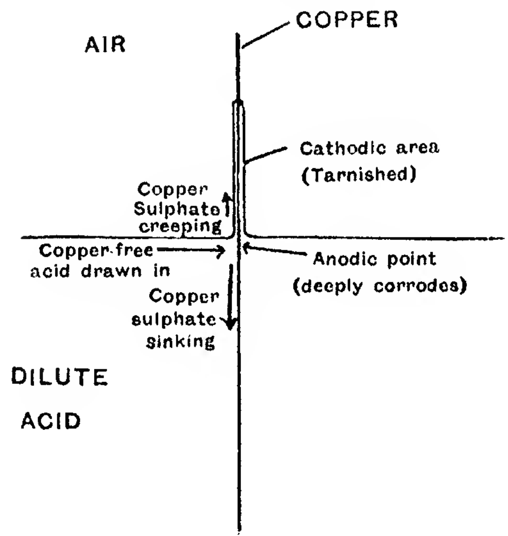

FIG. 2.

immersed in dilute sulphuric acid, the surface being wetted with the acid above the water-line, very rapid attack occurs just below the water-line, and the metal may be eaten through within a few days; the attack is comparatively slow if the copper is not wetted above the water-line. The explanation appears to be as follows. The aerated part above the water-line becomes cathodic, and the part immediately below the water-line is anodic, since it is just from this part that the copper sulphate will be removed most readily; the heavy solution containing that salt will sink downwards through gravity along the surface of the copper, whilst part of the salt will be sucked through capillary forces into the liquid film extending upwards over the copper surface; fresh acid free from copper salts will flow in laterally to replace the liquid which is sinking downwards, and thus the copper salt concentration just below the water-line is always kept low, and anodic attack will be concentrated on this part.

The explanation of water-line attack in dilute sulphuric acid just suggested is based on that given

[1] Water-line attack in neutral salt solutions often follows a course similar to that described in the section on "Corrosion due to drops resting on the surface."

y the author in a previous paper[1], but embodies so certain parts of the views put forward by E. A. Bolton[2] and K. M. Watson[3]; it attributes the special anodic attack just below the water-line to the preferential removal of copper salts from that point, but it also introduces the notion of selective aeration, and leads naturally to the consideration of differential aeration cells.

(B) Localised corrosion set up by differential aeration cells, analogous to those operative in the corrosion of iron and zinc.

(1) *Corrosion caused by contact with a non-conducting substance.*—The general analogy between the corrosion of copper and that of zinc, iron, or lead is clearly shown by experiments carried out under stagnant conditions, which exclude complications due to stirring. It has been demonstrated in previous papers that zinc, iron, and lead suffer special corrosion where they are in contact with non-conducting substances, such as glass, porcelain, or thread, which will tend to screen the metallic surface from diffusing oxygen. More recently the same effect was produced on copper, in the following way. A sheet of copper, cleaned with emery, was half immersed in a 3% solution of sodium chloride at an angle of 65°, being supported in this position by resting on a glass rod. The surface of the copper was wetted above the water-line, and solution naturally crept up between the rod and the sheet. The whole was placed in a large closed vessel to prevent evaporation. After two weeks the sheet was found to be very deeply attacked where it had rested on the glass rod, especially at the bottom portion of the rod, the place least accessible to diffusing oxygen. The other parts of the copper surface, both beneath the liquid surface and the wetted area above the water-line, although tarnished, were not sensibly corroded.

Analogous results have been obtained with brass. A piece of brass sheet, half immersed in 3% sodium chloride and supported against a glass rod in the manner just described, was found, after two weeks, to be deeply eaten away, where it had leant against the glass. Other pieces of brass, placed horizontally in 3% sodium chloride in porcelain dishes, with weighted watch-glasses resting on them at certain points, were found to be attacked locally around the points where the glasses had rested on the brass surface. In all experiments the (anodic) areas which had suffered attack were covered and surrounded by heaps of a loose green-blue salt, which was found to be mainly basic cupric chloride. It appears probable that the immediate anodic product was cuprous chloride, which shielded the surface on which it rested from oxygen, and thus promoted anodic attack on the brass below; any oxygen which commenced to diffuse through the salt was consumed in oxidising the cuprous chloride to basic cupric chloride.

The fact that corrosion through differential aeration can be set up in brass by contact with non-conductors is of great practical importance in connexion with brass condenser-tubes. It has long been known[1] that the entry of foreign bodies into the tubes of marine condensers is a most important cause of the initiation of corrosion; such foreign bodies include sand, coke, wood, cotton-fibre, shells, sea-weed, flakes of iron oxide, metallic sulphides or hydroxides. It is probable that the trouble usually arises when the vessels are in port; stagnant conditions then prevail in the tubes, and any foreign fragments which may have entered will rest on the bottom of the tubes and produce corrosion of the type described above. When once a considerable deposit of basic salts of copper or zinc has been produced, it is likely that the corrosion will continue at this point in preference to others, even if stagnant conditions cease to prevail. In practice it is often found that the trouble, once initiated, continues to increase long after the vessel has put to sea, in spite of the rapid passage of water through the tubes.

(2) *Corrosion due to drops resting on the metallic surface.*—A partial analogy between the corrosion of copper and that of iron is also observed on comparing the action of drops of sodium chloride solution placed on the surfaces of the two metals. In the case of iron (Fig. 3), as explained elsewhere,[2]

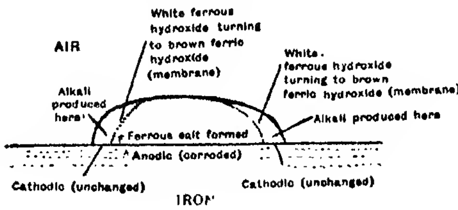

FIG. 3.

alkali is formed at the cathodic (aerated) margin of each drop, and ferrous salts at the anodic (unaerated) interior; where the alkali and ferrous salts meet, a membrane of white ferrous hydroxide, gradually oxidising to brown ferric hydroxide, appears; the corrosion is confined to the central portions within the membrane. This effect develops within a few hours. If a drop of sodium chloride solution is placed on a copper surface (Fig. 4), the action is much slower, and for some hours no change is observed, apart from the appearance of a fine series of "tarnish-colours" on the metal below the liquid. After a time, however, a cloudy white patch appears in the interior of the drop, and when once this white substance is observed on the surface of the metal,[3] the change proceeds comparatively rapidly. After a few days, there is a loose heap consisting of a pale blue-green precipitate in the centre of the drop, whilst the liquid around the heap is clear and contains alkali. If the precipitate is washed away, it is seen

[1]J. Inst. Metals, 1923, **30**, 272, 293.

[3]Frequently a very thin film or membrane appears on the upper surface of the drop before the precipitate appears on the metal itself; this film does not promote subsequent corrosion. The superficial membrane, which invariably appears sooner or later on the surface, is too thin to be analysed, but resembles a hydroxide-membrane.

Journal of the Society of Chemical Industry.

that the copper below it is distinctly corroded, whilst in the parts not covered by the precipitate the copper, although tarnished, has not been eaten away. The precipitate consists of a mixture of cuprous chloride and basic cupric chloride; in the early stages it is usually quite white, but darkens when exposed to the light; in the later stages, it is bluish or green.

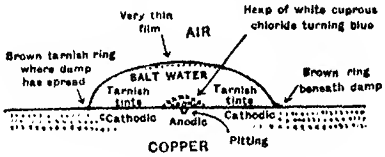

FIG. 4.

The explanation of these phenomena appears to be as follows. At first only a very minute current is set up between the margin of the drop and the interior, where the oxygen concentration is slightly lower than at the margin. But as soon as the anodic product, loose cuprous chloride, begins to accumulate, it will commence to shield the copper below it from oxygen, not merely by interfering mechanically with the diffusion of the oxygen, but also by absorbing it chemically with the production of the basic cupric chloride. Thus when once the precipitate has begun to form the action goes on at an increased rate.

If the interpretation just offered is correct, it would be expected that salts which will not yield a sparingly soluble cuprous compound as the anodic product will not produce serious localised corrosion of this kind. To test this matter, drops of $N/2$ solutions of potassium chloride, potassium sulphate, potassium nitrate, and sodium carbonate were placed on copper. After two days, the potassium chloride solution had produced marked local corrosion at the centre of the drop in the manner described above; but the other liquids had produced no real corrosion, although the copper was darkened below the sulphate and nitrate solutions. This observation supports von Wurstemberger's statement[1] that localised corrosion of copper and brass occurs most readily if the conditions are such as to produce deposits of sparingly soluble salts; he considers, for instance, that an alkaline reaction in the liquid, being favourable to the production of basic salts, is likely to promote the localisation of corrosion.

The nature of the tarnish-film produced within a drop of sodium chloride on the parts of the copper surface to which oxygen has access is of interest. A sequence of brightly-coloured concentric zones, rose, green, yellow, and blue, were produced, indicating, probably, that the film thickened as the edge of the drop was approached; the colours were due, no doubt, to interference or diffraction. After the precipitate had been washed away, the parts of the surface where the drops had rested were tested with different reagents. It was found that dilute sulphuric acid blackened the whole of the coloured region, hydrochloric acid removed the colours with slight blackening, whilst ammonia had no marked effect These three reagents behave in exactly the sam way towards the films produced by heating coppe in air—films which also show a fine series of col ours. Since the work of Pilling and Bedworth[1] has indicated that the film produced on heating copper in air is mainly cuprous oxide, it is legitimate to regard the behaviour of the tarnish-films towards the three reagents as indicating that the tarnish-films also consist of cuprous oxide.[2] At the extreme margin of the drop, where the moisture had crept outwards from the original position of the boundary, there was observed a narrow zone of a brownish colour, which was dissolved away by dilute sulphuric acid without blackening, and which was therefore presumably cupric oxide.

Results analogous to those observed on copper were obtained when drops of 3% sodium chloride were placed on a brass surface; a blue-green precipitate appeared in the centre of the drop, and below it the brass was found to have suffered distinct alteration, giving rise to a light brown adherent layer. The fact that the placing of drops on brass may initiate corrosion is of some importance, in view of the fact that some marine engineers advocate the draining of condenser tubes when ships are in port. If the tubes are dried quickly, this is no doubt a good plan; but if the tubes are left for any considerable time with wet and dry patches on the internal surface, the practice may initiate just the type of corrosion whicl it is desired to avoid.

(3) *Corrosion due to an uneven surface.*—Pieces of brass rubbed with coarse emery paper and immersed in 3% sodium chloride solution contained ir a shallow dish, were found to be corroded in a manne dictated by the direction of the grooves left by th emery. The blue-green corrosion product was seen t run largely in straight lines following the grooves and on rubbing off this layer of salt the underlying brass was itself found to be darkened within the grooves and almost unchanged between them. This i precisely analogous to the observation previousl made on iron,[3] on which metal the rusting alway tends to follow the grooves left by emery-treatment The reason in both cases is, of course, that th interiors of the grooves are less accessible to th diffusion of oxygen than other parts of the surfac and therefore become anodic. The observation has certain practical importance, because Maass an Liebreich[4] consider that internal unevenness i condenser tubes is a serious cause of corrosion, an state that one of the most important advantages tinning the tubes is that the unevennesses are filled u

Effect of the corrosion-product in promoting corrosio

Several examples have already been given of th way in which, when once the formation of cupro chloride has commenced at a place, corrosion procee there apace. The explanation offered is analogo

[1] Z. Metallk., 1922, **14**, 23, 59.

[1] N. B. Pilling and R. E. Bedworth, J. Inst. Metals, 1923, **29**, 529.
[2] Many text-books say that cuprous oxide dissolves quickly in ammoni this statement would not appear to apply to the oxide in the form an adherent film.
[3] U. R. Evans, Proc. Camb. Phil. Soc., 1924, **22**, 54.
[4] Z. Metallk., 1923, **15**, 245.

› that put forward previously to account for the ‹fect of wet rust in promoting further rusting; the ›rrosion-product in each case tends to prevent the ›cess of oxygen to the unchanged metal below, and ›us allows anodic attack to proceed. The shielding › the metal from oxygen is probably not merely a ›se of mechanical hindrance to diffusion; it is ›kely that the oxygen is absorbed chemically by the ›uprous chloride or by the ferrous hydroxide.

The effect of the corrosion-product in promoting ›ibsequent corrosion of copper, brass, and bronze ›as been noticed under many different circumstances. › has long been known that copper or bronze exposed › the atmosphere sometimes develops at certain ›laces a greenish deposit, which gradually spreads ›om these points until it covers the whole surface; ›iis spreading of the area under attack has often been ›escribed as a disease. Rathgen[1] has examined ›veral hundred specimens of the greenish deposit, ›nd has found chloride present in every case; the ›istence of chlorides in the deposit found on ancient ›onze articles at the British Museum has also been ›tablished by recent investigators, who regard the ›loride as the active agent in corrosion.[2] The ›esent author[3] has observed that when specimens › copper are exposed to moist air containing hydrogen ›loride, serious corrosion occurs at certain points ›hich become covered with a thick green deposit, ›hilst other parts are only superficially attacked. ›any years ago Tilden,[4] after lengthy examination › the action of warm sea-water on copper, brass, ›d bronze, came to the conclusion that the basic ›loride of copper was the main corroding influence. Bengough and his colleagues,[5] as the result of ex›nded and careful study of the corrosion of condenser ›ibes, have come to the conclusion that some of the most important types of localised corrosion are to be attributed to the presence of basic salts adhering to the surface of the tube.

Other influences causing localisation of corrosion.

Since the total rate of attack upon copper and brass articles by most liquids (as measured by loss of weight) is very small, corrosion will only become of serious import if it is localised upon a limited area of the article in question. Certain causes of localisation have already been enumerated, but for the sake of completeness, two other influences, which have been urged by other writers, may be mentioned.

Philip[6] and also Lasche[7] have pointed out that particles of carbonaceous substances (coke, coal, graphite flakes, etc.) settling on the bottom of a brass condenser tube have a particularly disastrous effect, and have attributed this to the production of corrosion couples, the carbonaceous substance acting as cathode. Furthermore, the local removal of the oxide or other scale which should exist all over the surface of a healthy condenser tube is likely to lead to the concentration of corrosion at the exposed place; this removal may occur by mechanical means (erosion) as suggested by Bengough, or by stray electric currents, or by the presence of an unduly acid water, as suggested by Lasche; the presence of a *weakly* acid reaction is, however, probably favourable to the life of the tube, as has been indicated by von Wurstemberger.

The author desires to thank Mr. C. T. Heycock, F.R.S., for information regarding the condenser at Cambridge, and Dr. Bengough and Mr. Stuart for information regarding marine condensers.

Summary.

Localised corrosion of copper and brass articles may occur :—

(A) By *preferential removal* of copper salts from certain points, thus producing a concentration cell; the points of low concentration are the anodes of the cell, and suffer attack. This removal may occur:

(1) by *high local velocity of water* (an example is described of the corrosion of an externally cooled condenser-tube, just opposite to the cooling-water inlet);
(2) by *gravity* or *capillary forces* (*e.g.*, in water-line attack by acids).

(B) By *differential aeration*, the points shielded from oxygen become anodic and suffer attack. Differential aeration cells may be set up:

(1) where *foreign bodies* rest on the metallic surface (*e.g.*, sand, shells, etc., in marine condenser-tubes);
(2) where *drops* of liquid rest on a dry metallic surface;
(3) where the *surface is uneven* (*e.g.*, corrosion in scratches left by emery treatment).

Cuprous chloride, the corrosion product, when once formed, serves to screen the underlying metal from oxygen, and thus to promote further corrosion.

Other probable causes of localised corrosion include :—

(C) *Contact with conducting bodies* (*e.g.*, effect of carbonaceous fragments in condenser tubes).

(D) *Local removal of a protective skin.*

SEPARATION OF COBALT FROM NICKELIFEROUS ORES BY THE PURPUREO-COBALT CHLORIDE PROCESS.*

BY GILBERT T. MORGAN AND J. D. MAIN SMITH.

Metallic cobalt and its salts are obtained commercially from arsenical cobalt ores containing considerable amounts of nickel and iron together with smaller quantities of other metals such as copper and bismuth. After preliminary treatment to remove part of the arsenic, a calcined speiss is obtained, consisting largely of arsenides and oxides. This speiss is dissolved in hot concentrated hydro-

* Read at a meeting of the Birmingham Section on April 4, 1924.

chloric acid, iron and arsenic are removed as ferric arsenate by hot milk of lime, the metals of analytical group II. removed as sulphides with hydrogen sulphide, and the remaining iron as ferric hydroxide by milk of lime. From the final liquid the peroxides of cobalt and nickel are fractionally precipitated with bleach-liquor, cobalt being separated nearly quantitatively before nickel.

A description of this process appears in Tilden's "Manual of Chemistry" (1889) as being the oldest and most efficient in use at that time, but the process is not mentioned as being in commercial use in later text-books. A very similar process has been worked on a large scale for over half a century and is still in use by Messrs. Henry Wiggin and Co., Ltd., of Birmingham, to whose courtesy we are indebted for the gift of the cobalt speiss used in the following investigation.

In the course of our researches on residual affinity and co-ordination, in which cobalt has played an important part in the elucidation of the constitution of mordant dyes (see Chem. Soc. Trans., 1921, **119**, 704; 1922, **121**, 160, 2857, 2866), considerable quantities of various cobaltammines have been prepared and a large-scale process has been devised for the rapid and economical preparation of purpureo-cobalt chloride (chloropentamminocobaltic chloride), $[CoCl,5NH_3]Cl_2$. This carmine-red complex salt, originally discovered in 1851 almost simultaneously by Genth in America, Fremy in France, and Claudet in England, was utilised by the last of these for the separation of cobalt from its ores. This method is frequently referred to in the literature relating to cobalt, although the process does not appear ever to have been in commercial use, due doubtless, not to the incompleteness of the separation, but to the costly nature of the process, excess of hydrochloric acid, ammonia, ammonium carbonate and chloride being necessary.

The improved process described below can be worked at a small fraction of the cost of existing methods for the preparation of purpureo-cobalt chloride, and this could be further greatly lessened by the recovery of the ammonia, calcium chloride becoming the sole waste product. A comparison with Biltz's process, probably the best known and most efficient (see "Laboratory Methods," p. 173), is subjoined

Reagents	Biltz's process.	New process.
Cobalt as chloride	1 g.-atom	1 g.-atom
Ammonium carbonate	3 mols.	nil.
Ammonium chloride	17 mols	3 mols
Ammonia	11 to 14 mols.	8½ mols.
Hydrochloric acid	20 to 35 mols	nil
Hydrogen peroxide	nil.	0·6 mol. or nil.
Water, including that in reagents (approx.)	600 mols.	60 mols

Biltz's process thus involves an excessive use of reagents and large volumes of liquid. These solutions have successively to be oxidised by prolonged aeration, evaporated to dryness, made up to the original volume, and boiled repeatedly. The yield of purpureo-cobalt chloride varies considerably; 70 to 80% of the theoretical is usual, although much smaller proportions are often obtained owing to incomplete oxidation and loss of ammonia during aeration. By the new process a yield of over 90% is invariably obtained, and 94–95% is usual. For the preparation of about 50 grams, Biltz's process requires about seven hours, and much larger quantities cannot be conveniently made in the laboratory owing to the bulk of solution. By the new method, the same amount can be made in less than an hour, and 500 grams are obtainable with ordinary laboratory vessels in about four hours.

The new process is well adapted for large-scale operation, and is under complete control at all stages. The free ammonia and the combined ammonia in the cobaltammine salt and ammonium chloride are readily recoverable. On boiling with the calculated amount of chalk or milk of lime, the purpureo cobalt chloride readily yields ammonia, hydrated cobaltic oxide being precipitated and calcium chloride passing into solution. Apart from normal wastages, the only reagents, other than hydrochloric acid necessary for solution of the ore, are hydrogen peroxide and chalk or lime. On a works scale the use of hydrogen peroxide, which, however, is now cheaply available, could be dispensed with in favour of aerial oxidation, under pressure if necessary for rapid working. The presence of metals yielding hydroxides soluble in ammonia, such as nickel and copper, affects neither the amounts of reagents nor the yield and purity of the product. Metals yielding hydroxides insoluble in ammonia, may be removed by filtration after oxidation, or may be dissolved out of the product by dilute hydrochloric acid, in which the product is almost insoluble. The only metals which could be present in the final product are rhodium and iridium, which form similar ammines. If present in the ores, these metals could be isolated by this precipitation, as both are readily separable from cobalt.

Cobalt-nickel ores containing a high percentage of nickel are usually worked for nickel by the Mond carbonyl process, cobalt accumulating in the residues, whereas ores containing a high percentage of cobalt are worked mainly for cobalt by the Wiggin process. The crude cobalt oxide thus produced invariably contains a considerable amount of nickel, which is largely removed by extraction with dilute hydrochloric acid, but analytically nickel-free cobalt oxide is never obtained. We have found, however, that analytically pure cobalt oxide is obtainable practically quantitatively by the purpureo-cobalt chloride process, and that the presence of nickel in the original ore or mixture, in amounts varying from 5 to 50% of nickel, does not affect the yield or purity of the cobalt product. The residual liquors from precipitated purpureo salt contain 5 to 6% of the original cobalt content and the whole of the nickel, together with ammonium chloride. After recovery of the ammonia by boiling with milk of lime, the mixed oxides of cobalt and nickel accumulated from several batches may be separately treated for recovery of the bulk of the cobalt, or returned to the ore solutions for repeated treatment, depending on the

relative proportions of cobalt and nickel. With ores very low in nickel, the mixed oxides would advantageously be returned to the ores for subsequent treatment until the proportion of nickel in the residues was approximately equal to that of cobalt. The mixed oxides are then separately treated for recovery of the cobalt, and the final mixed oxides, containing over 90% of nickel oxide, used metallurgically as nickel, since few nickel alloys require to be entirely free from cobalt.

Four chemical operations are involved in the process:—solution of the ore, removal of arsenic, formation of the insoluble cobalt compound, and its decomposition to yield cobalt oxide. On boiling the calcined ore (speiss) with concentrated hydrochloric acid, the cobalt and nickel peroxides are converted into the lower chlorides, the chlorine liberated oxidising the ferric arsenide to ferric arsenate, which remains in solution in the acid liquor, and is precipitated therefrom after nearly neutralising and boiling. A deficiency of chlorine may be corrected by employing bleach-liquor as part of the neutralising reagent, since it is essential that no arsenite be present. A deficiency of iron necessary for complete precipitation of the arsenic as ferric arsenate is corrected by the addition of a slight excess of ferric chloride. A satisfactory speiss should contain sufficient available oxygen to convert all the arsenic to arsenate and enough iron to combine therewith. The formation of the cobalt compound consists in the addition of six molecules of ammonia to each molecule of cobaltous chloride, the simultaneous oxidation and hydrolysis of the hexamminocobaltous salt to the aquopentamminocobaltic salt, and the conversion of the latter by hot ammonium chloride into insoluble chloropentammino- or purpureo-salt $[CoCl,5NH_3]Cl_2$. This salt is readily decomposed by alkalis or calcium carbonate on boiling, with precipitation of cobaltic hydroxide.

Separation of cobalt from mixtures of cobalt and nickel.

1. *Mixture containing 50% of nickel.* To a solution of 23·8 g. of hexa-aquocobaltous chloride and 23·8 g. of hexa-aquonickel chloride in 50 c.c. of water were added 16 g. (=3 mols. per atom of Co) of ammonium chloride, forming after boiling a bluish-green liquid, which was cooled to room temperature before the addition of 17 c.c. of 6*N* hydrogen peroxide solution (=1·7 g. H_2O_2=½ mol.). The mixture was immediately poured into 39 c.c. of 18*N* ammonia solution (=11·9 g. =7 mols.), the liquid turning dark brown, becoming hot and effervescent. On boiling vigorously the solution turned dark red and a carmine-red crystalline precipitate of purpureo-cobalt chloride separated. When nearly all the free ammonia had been removed by boiling, the hot liquid was filtered and the precipitate washed with a few c.c. of 2*N* hydrochloric acid solution to remove the adherent mother-liquor, and the filtrate and washings were allowed to cool. The precipitate was well drained at the pump and then dried at 160° C.; the yield was 20·8 g. (=83%). The required 17% of the original quantities of the ammonia (=7 c.c.) and hydrogen peroxide (=3 c.c.) solutions was added to the still ammoniacal cold filtrate, and the mixture again boiled till nearly all the free ammonia was removed, purpureo-cobalt chloride again separating. After washing with a few c.c. of 2*N* hydrochloric acid solution and drying at 100°, the precipitate weighed 2·7 g. (11% yield), the total yield of the cobalt compound thus being 94%, or precisely the same as if the original solution had contained no nickel.

2. *Mixture containing only 5% of nickel.*—The foregoing process was repeated with the same quantities of all the reagents, except that only 2·4 g. of the nickel salt were used, the yield of cobalt compound being again 94%.

3. *Separation of cobalt from cobalt speiss.*—To 53 g. of finely powdered cobalt speiss (calcined arsenical ore) containing 12·5% of cobalt (=22·5 g. Co) were added 160 c.c. of concentrated hydrochloric acid solution (=10*N*), and the mixture was boiled vigorously and stirred till the green liquid became pasty. It was then boiled with 50 c.c. of water and filtered. The residue was boiled with a further 40 c.c. of the acid till again pasty, then with 20 c.c. of water, and filtered. The combined filtrates were nearly neutralised with powdered limestone, boiled to precipitate ferric arsenate, and filtered. The liquid on testing still contained both iron and arsenic, and further small amounts of limestone were added and the liquid was boiled till the final filtrate was free from arsenic, a slight deficiency of iron necessary for the removal of all the arsenic as ferric arsenate being corrected by the addition of a slight excess of ferric chloride solution. The filtrate was diluted to 300 c.c. and 61 g. of ammonium chloride (=3 mols. per atom of Co) dissolved in it by boiling. After cooling, 65 c.c. of 6*N* hydrogen peroxide solution (=½ mol.) were added, and the mixture was immediately poured into 170 c.c. of 18*N* ammonia solution, *d.* 0·880 (=8 mols.), the mixture becoming hot, dark brown, and effervescent. It was then boiled and stirred vigorously till nearly all the free ammonia was removed, and the purpureo-cobalt chloride which separated removed by filtration, washed with 50 c.c. of 5*N* hydrochloric acid solution to remove ferric hydroxide, and dried at 100°, 79·5 g. (84% yield) being obtained. The filtrate when cold was re-oxidised with 12 c.c. of the hydrogen peroxide solution after the addition of 34 c.c. of the ammonia solution, boiled till the free ammonia was nearly removed, and filtered. The precipitate was washed with a few c.c. of 2*N* hydrochloric acid solution to remove mother liquor and dried at 100°, 10·3 g. (11% yield) being obtained. The total yield of purpureo-cobalt chloride was 95% calculated on the cobalt content of the speiss, the separation of cobalt being practically quantitative.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research and to Messrs. Brunner, Mond and Co. for grants which have helped to defray the expense of this investigation.

THE VOLATILE MATTER AND ASH CONTENTS OF SAMPLES OF COAL FROM THE SAME SEAM.

BY T. J. DRAKELEY AND J. R. I. HEPBURN.

The calculation of the percentage of volatile matter (V) in a sample of coal, on an ash- and moisture-free basis, has usually been made by means of the formula :—

$$V_1 = 100(v_c - w)/(100 - a_c - w), \ldots\ldots\ldots\ldots (1)$$

where v_c is the percentage of volatile matter including water in the crude coal, a_c the percentage of ash, and w the percentage of moisture.

In view of the fact that the volatile matter content on an ash- and moisture-free basis is one of the factors which may be used in the classification of coals (see, for example, Parr, J. Ind. Eng. Chem., 1922, **14**, 919), it is of importance that the accuracy of this formula should be examined.

The effect of moisture in the coal is apparently precisely expressed by the equation ; and in the following investigation dry coal samples have been used, so that the formula under examination becomes :—

$$V_2 = 100\,v/(100 - a) \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

where v is the percentage of volatile matter and a the percentage of ash in the crude dry coal.

Equation (2) takes no consideration of the fact that incombustible volatile products are usually evolved from the incorporated mineral matters (such as hydrated silicates of aluminium) when they are heated to incandescence in the absence of air. In such cases, the yield of volatile matter from the coal naturally appears to increase as the ash content rises, since increasing quantities of water of hydration of mineral matter are accepted as volatile constituents of the coal substance. Reference may be made to column six of Table III. which illustrates the application of equation (2) and the consequent apparent abnormal increase in the volatile content of the coal.

Furthermore, the ash constituents, whether introduced as mineral matter inherently present in the plant residues from which the coal was formed or as extraneous inorganic compounds incorporated with the coal substance, are regarded as identical compounds. The former quantity is, however, so small that only a very minute error is made in classing all the mineral matter together.

For an average sample of mined coal little variation is observed in the volatile content of the pure coal substance throughout the seam, but if the sample is separated into fractions differing only slightly in specific gravity, a considerable divergence results. This has been shown to be due to a variation in the proportion of the different banded constituents of the coal in the samples.

Volatile matter and ash contents of coal yielding a small ash.

The coal studied was a Notts. hard (steam) coal. A large block was cut into pieces of about 2 cm. size, which were separated by flotation in a series of mixtures of alcohol and chloroform into fractions of increasing specific gravity (*cf.* Blyth and O'Shea, Trans. Inst. Min. Eng., 1919, **57**, 261).

Ten samples having specific gravities ranging from 1·250 to 1·300 and increasing by regular intervals of 0·005 were secured. These ten samples constituted 85% of the original coal, and it was found that no visibly clean coal remained having a specific gravity higher than 1·300. The samples were dried in the steam oven to remove chloroform and alcohol, and powdered to pass a 30-mesh sieve.

The volatile matter and ash contents and the true specific gravity were determined for each of the ten samples after drying in a steam oven for 3 hours, and cooling in a desiccator over sulphuric acid. This method of drying was found by preliminary experiments to yield, in the case of the particular coal studied, results identical with those obtained by drying for a considerable time over sulphuric acid at the ordinary temperature.

True specific gravity.—The true specific gravity of each coal sample was determined in an ordinary specific gravity bottle, using air-free distilled water. The work of Drakeley and Jones (J., 1923, 163T) indicates that, for pieces of coal of moderate size, saturation is most easily effected by immersing in boiling water for a minimum period of one hour and a quarter. In the case of coal powdered to pass a sieve of 30 meshes to the inch, it was found sufficient to treat the coal for half an hour with boiling water, before determining its true specific gravity.

Determination of the volatile matter.—The method employed was that of Bone and Silver (Chem. Soc. Trans., 1921, **119**, 1145), which had been shown to yield results of high accuracy. It was found necessary to raise the temperature very gradually to prevent explosive evolution of the volatile matter from the coal. The temperature was maintained at 900° C. for about 7 hours to ensure complete elimination of the volatile matter.

Ash content.—The coke samples obtained in the previous determination were powdered to pass a 30-mesh sieve, dried for a short time in the steam oven, and incinerated in open porcelain dishes in a gas-muffle furnace for 3 hours, at the maximum temperature of the furnace (910° C.).

The results of the above determinations are given in Table I.

Throughout the paper the significance attached to each of the following symbols is :—

p = percentage of volatile matter yielded by dry shale.

v = percentage of volatile matter in dry crude coal.

a = percentage of ash yielded by dry crude coal.

V = percentage of volatile matter on ash- and moisture-free basis (calculated).

The number affixed to V (*e.g.*, V_2) indicates the equation used in the calculation.

TABLE I.

No.	Specific gravity. Apparent.	Specific gravity. True.	Volatile matter in dry coal. v%.	Ash on dry coal. a%.	Ash and moisture free basis. V_2.
1	1·255	1·322	34 43	1·30	34 89
2	1·260	1·325	34 82	1·02	35 18
3	1·265	1 335	31·37	1·32	31 79
4	1·270	1·332	30·68	0 97	30 98
5	1 275	1·348	31 17	1·09	31 52
6	1·280	1·343	27·43	1·83	27·94
7	1·285	1·348	28·62	2 92	29·48
8	1·295	1·347	31·82	2·41	32 96
9	1 300	1·347	30 67	2 01	31 30

The volatile matter content, V_2, of the ash-free ry coal shows a considerable variation, to an xtent which cannot be accounted for even by any rror in the accuracy of the equation.

Samples 1 and 2 were characterised by low specific ravity, low ash content, and high volatile matter. 'hey yielded good cokes. The colour of the ash 'as red-brown in each case, but a few white particles 'ere present. On the other hand, samples 6, 7, 8, nd 9 possessed relatively low volatile matter and igh ash contents and high specific gravity (nearly onstant at 1·348). They yielded poor cokes and he ash was almost white in colour.

It was thought that the anomalous results given ı Table I. might be attributed to the varying uantities in each sample of the four ingredients f banded bituminous coal (see Stopes, Proc. oy. Soc., 1919, **B 90**, 470).

Tideswell and Wheeler have shown (Chem. Soc. rans., 1919, **115**, 619) that the bright constituents f bituminous coal (clarain and vitrain), isolated y Stopes from the thick seam (Hamstead Colliery), ssess specific gravities markedly lower than that the dull variety (durain). In addition, the bright oal has lower ash and higher volatile matter contents han the dull coal.

Accordingly, the Notts. hard coal was examined, nd samples of the four ingredients separated from ;, following the procedure prescribed by Stopes *loc. cit.*). The chief constituents were durain and larain, a small proportion of vitrain being interanded with the clarain in layers about 5 mm. in hickness. Very little friable fusain was found ut a quantity of the hard variety of fusain recently escribed by Sinnatt (Trans. Inst. Min. Eng., 1922, **2**, 156) was separated and analysed. The amount this fusain, chiefly associated with durain, was tremely difficult to determine.

In Table II. the properties of these constituents e given. There is a marked parallelism with deswell and Wheeler's figures (*loc. cit.*, p. 630). ıe clarain yielded a brownish-red ash, vitrain own, durain pure white, and fusain (friable riety) pale grey.

TABLE II.

	Specific gravity Apparent.	Specific gravity True	Moisture. %	V. %	a %	V_2. %
rain	1 291	1·343	7 02	29 30	0 80	29 57
raln	1 248	1 301	4 06	34 14	0 79	34 42
rain	1·257	1 345	2 50	32 00	2 78	33 00
saln	—	1 558	1·54	13 32	11 3	15 00
saln (hard)	—	1 452	2 06	13 67	5 38	14 45

A comparison of the results given in Tables I. nd II. shows that samples 1 and 2 of Table I. consted mainly of clarain, samples 6, 7, 8, and 9 of ırain with varying amounts of fusain. A fairly good separation of this particular coal into its two most important constituents, clarain and durain, may thus be readily effected in the laboratory by a carefully regulated flotation process.

This conclusion agrees with Lessing's work (Trans. Inst. Min. Eng., 1921, **60**, 288) on the separation of a coking slack from South Yorkshire into two fractions, by flotation in mixtures of carbon tetrachloride and petroleum spirit of d 1·35 and 1·50 respectively (*cf.* also Beet and Findley, *ibid.*, 1921, **60**, 213; Küppers, Glückauf, 1916, **52**, 599).

Conclusions.

As a result of the examination of samples of clean coal from the same seam of increasing specific gravity, it has been shown that the volatile matter content on an ash- and moisture-free basis does not admit of mathematical treatment. The difficulty is due to the separation of the coal sample into fractions containing varying proportions of the four different banded ingredients of the coal substance.

Relation between volatile matter and ash contents of coal yielding a high percentage of ash.

An examination of a large bulk sample (2 tons) of the same coal (Notts. hard steam coal) as used in the earlier part of the work, showed that it

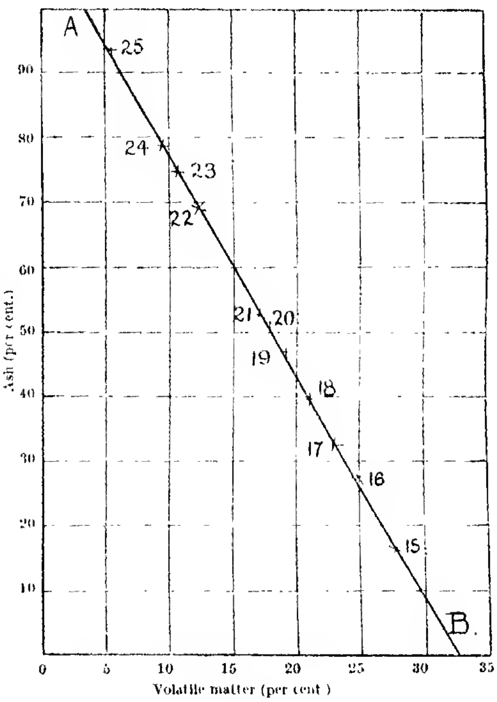

FIG. 1.

contained so small a proportion of inorganic partings, consisting chiefly of calcium carbonate (*cf.* Sinnatt, J., 1921, 1 T) with a mere trace of iron pyrites, as to render their determination impossible. The ash-

producing impurity consisted almost entirely of shale, apparently from the roof and floor of the seam. The iron pyrites was kept for the final experiments.

A sample selected for examination was considerably interbanded with shale. It was cut into roughly cubical pieces of about 2 cm. size, and experimental data for 10 fractions of specific gravity ranging from 1·35 to 2·25 were compiled (see Table III.). The colour of the ash from the 10 samples was a uniform very pale brown, indicating the absence of appreciable quantities of iron.

25	—	2·764	5·12	93·96	—	—
					Average	32·60

The figures for the volatile matter of the "pure coal" (V_2) contained in the samples steadily increased in an unaccountable manner.

The exact relation between volatile matter content (v) and ash content (a) is shown in Fig. 1. The points in the graph which are numbered to agree with the reference numbers of Table III. lie on or close to the straight line AB. The volatile matter content of the pure coal of zero ash content is found by extrapolation from the graph to be 32·6%. This value is close to that previously obtained for durain (Table II.).

A sample of almost pure shale was obtained, and is represented on the figure by the point numbered 25. It appears from the regularity of the graph that the samples consisted of mixtures of shale and pure average coal, and consequently a formula may be developed to express the relation between the volatile matter and ash contents of the coal.

Thus if x is the percentage of pure coal and p the percentage yield of incombustible volatile matter from the shale, the following equation may be deduced :—

$$V_2 = [v - ap\,(100-p)]/[100 - a - ap/(100-p)] \quad \ldots\ldots\ldots (3)$$

The pure coal substance is assumed to possess a negligible ash content. For vitrain and clarain (see Table II.) this statement is true, whilst Lessing (Chem. Soc. Trans., 1920, 117, 256) has shown that the mineral ingredient of durain and fusain is of similar constitution to shale, and therefore it is correct to regard durain and fusain as mixtures of a pure organic substance with shale.

Equation (3) represents a straight line graph and can therefore be made to apply to the line AB (Fig. 1) by suitable adjustment of the constant p. From the position of the line AB, the value of p is 4·93%. This value agrees fairly well with the direct determination of the volatile matter of the purest sample of shale discovered in the mined coal (5·18%). Even this sample must have contained a little carbonaceous matter which, however, was invisible. Tests proved the absence of a mineral carbonate in the sample of shale, so the difference in the two values cannot be ascribed to this impurity.

By substitution of the result 4·93 for p in equation (3), the volatile matter content of the pure coal in each sample (V_2) was calculated, and the values are given in Table III. The results for the percentage of volatile matter in the pure coal are now constant and therefore formula (3) is suitable for calculating the volatile matter content on an ash-free basis.

To correct the results for moisture it is necessary to subtract w from the numerator and from the denominator in equation (3).

The volatile matter content of shale.

The percentage loss of weight (p) when shale is heated appears to be subject to greater variation than was at first anticipated. Parr (*loc. cit.*) accepts a constant value of 7·4% for p. Drakeley (Trans. Inst. Min. Eng., 1918, **56**, 52) found that for Lancashire shales, the loss on heating air-dried samples averaged about 9·5%, and subsequent experiments show that, after more complete drying such as was resorted to in this investigation, the loss was reduced to about 7·2%. Küppers (*loc. cit.*) calculated the value of p as 6·8% for Westphalian shales.

In the present investigation, however, the incombustible volatile constituents of the shale only amounted to 4·93%. The results may be exceptional, but sufficient evidence has not been obtained for definite statements to be made.

Relation between volatile matter and ash content in the presence of pyrites.

For a mineral impurity which loses weight on further open ignition after all the volatile matter has been evolved by heating in the absence of air (*e.g.*, pyrites), a modification in equation (3) becomes necessary.

The amount of pyrites present in a coal sample is usually not large, but it is not regularly distributed throughout the coal.

The following values (averages of six determinations) for the volatile matter and ash contents were obtained by igniting a sample of pyrites in the absence and presence, respectively, of air; "volatile matter" content, 16·70%; ash content, 67·42%; from which it was calculated that the percentage of pure iron pyrites (FeS_2) in the original sample was 89·3%. The sample contained 42·61% of iron, corresponding to 91·3% of FeS_2.

The impurity present in the pyrites amounted to 8·7%, and assuming that the "volatile matter content" of pure iron pyrites is 17·78% and of the original sample 16·70% the volatile matter content of the impurity is 5·4%, that is, its ash yield is 94·6%.

Since the ash yield of dry shale from this seam amounted to 95·07%, it would appear that the impurity in the sample of pyrites was shale. Hence the experimental data for mixtures of coal and iron pyrites will require correction for the shale present in the iron pyrites.

Formula (3) may be modified to include iron yrites as well as shale as a possible impurity in ie coal by subtracting $f\{0{\cdot}38\text{–}1{\cdot}38\ p/(100\text{-}p)\}$ from e numerator and $f[0{\cdot}76\text{–}1{\cdot}38\ p/(100\text{-}p)]$ from the nominator, where f is the percentage of iron in e original coal.

The use of this modified equation gave a value f 32·69% for the volatile matter content of the coal, hich agrees well with the value of (32·60) given Table III.

The equation may be expressed in terms of the ercentage of sulphur (s) in the coal, although this alue will now include the "organic" sulphur. t will then be necessary to replace f by s, 0·38 by ·44, 0·76 by 0·87, and 1·38 by 1·58.

For ordinary industrial purposes it will probably e sufficiently accurate to use the value 0·075 for $p/(100\text{-}p)$. In each case, the validity of the equation ests on the assumption that the iron pyrites burns ompletely to iron oxide, and that no sulphate emains in the ash. A slight retention of the sulphur n the ash would not appreciably affect the equation. ncidental experiments seemed to show that at 10° C. little sulphate remains in the ash and, furthernore, a high percentage of silica in the ash appaently tended to prevent the formation of sulphate ven when calcium carbonate was one of the subtances in the original mineral matter.

Summary.

(1) The volatile matter contents of samples of lean coal do not admit of mathematical treatment wing to the fact that the sample may be composed f any one, or any mixture, of the four different anded constituents of the coal.

(2) An equation is given for calculating, on verage samples of dry coal containing no iron yrites, the volatile matter content of the coal on n ash-free basis.

(3) The percentage of volatile matter yielded by lry shale appears to vary considerably. The variaions may be due to the different methods employed n the initial drying of the shale.

(4) For crude coal samples, containing iron pyrites and other impurities such as shale, modified equations are given for calculating the volatile matter content of the coal on an ash-free basis.

TRAVANCORE ESSENTIAL OILS.—I. OIL FROM THE SEEDS OF *ELATTARIA CARDAMOMUM* (CARDAMOMS).

BY K. L. MOUDGILL, B.A., B.SC., A.I.C.

Three varieties of cardamoms, viz., the "wild," the "Malabar," and the "Mysore," are available in Travancore. The plant occurs in its wild state at high elevations, in almost all the interior and evergreen forests. The other two varieties are cultivated. Most of the plantations containing the Malabar variety were started originally with the cuttings taken from the wild plants and, therefore, these varieties resemble each other.

A fourth variety, called the "Hybrid," has recently been noticed on plantations where the "Mysore" and "Malabar" grow side by side. No attempt has, so far, been made to cultivate this variety.

A sample of cardamom oil of unknown origin received by the author in August, 1922, from the Director of Industries, was a light yellow, viscous liquid, with an odour of cardamoms, but its constants were outside the limits recorded for normal oils (Table II., column 6). With a view to ascertain the variety from which the oil had been distilled, a comparative study of the oil from the seeds of the three varieties was made, and has shown that the constants of this oil agree with those of the oil from wild cardamoms. Analysis has further shown that, besides the known constituents, the Malabar and Mysore oils contain in the combined state, a small quantity of an acid (mol. wt. 182) having a strong odour of cumic aldehyde.

The fruits (about 5 lb. each of Mysore and Malabar cardamons, and ½ lb. of wild cardamoms) were received two months after plucking, and the oil from these was obtained within a week after their arrival. The fruits were husked, the seeds crushed in a coffee-mill and distilled with steam. The use of an oil bath and of superheated steam (170°–180°) was helpful. Table I. gives the characters of the fruits and the seeds of the different varieties of cardamons, and Table II. gives the constants of the oils immediately after distillation and on keeping.

* These figures are taken from a certificate by W. H. Simmons to Essenflour Products, Ltd., and published in the *Perfumery and Essential Oil Record*.
† The oil dissolves in alcohol but turbidity reappears on adding more alcohol. The lower figures give the volumes at which turbidity reappears.

The Mysore and Malabar cardamom oils thus fall within the limits of known oils, but the oil from wild cardamoms is abnormal. The constants of the fresh oil from the latter agree very closely with those of the sample received from the Industries Department, and it is, therefore, concluded that the sample under examination had been obtained from the wild seeds. Further, the constants of the oils from Mysore cardamoms grown in Travancore, and those grown in Mysore (compare Simmons, Table II.) agree very closely. The Malabar oil was more penetrating in odour than the Mysore oil.

Aqueous distillates.—The chloroform extract of the aqueous distillate from Malabar oil yielded a small quantity of an oil ($n_D^{28} = 1{\cdot}4620$) which deposited crystals of borneol, m.p. 198°. The aqueous distillate from Mysore oil yielded traces of an oil but no borneol.

Combined acids.—The Malabar oil was saponified with alcoholic caustic potash, the alcohol evaporated off, and the residue extracted with water; the aqueous extract was washed with ether to remove adherent oil, acidified with excess of dilute sulphuric acid and distilled with steam. An oil, with a very strong odour of cumic aldehyde, was recovered along with the aqueous distillate. The latter did not give a positive test for formic acid (*cf.* Parry "The Chemistry of Essential Oils," Vol. I., p. 104), and was shown to consist entirely of acetic acid.

The oily acid which possessed the odour of cumic aldehyde could not be purified easily, and has not yet been identified. It yielded a silver salt containing 37·3% Ag (mol. wt. = 182 if the acid is monobasic). The Mysore cardamoms also gave a very small quantity of the same oil.

Examination of the oil.—The residual oil after saponification had a very strong odour of the lily of the valley. Distillation under atmospheric pressure yielded the following fractions :—

No.	B p.	Yield. %	n_D^{28}	a_D^{28}	d_4^{28}
1	Up to 180° ..	37	1·4640	+25·2°	0 8609
2	180°–230° ..	52	1 4730	+46·5°	0·9325
3	Above 230° ..	3	1·4830	—	—
4	Residue by difference ..	8	—	—	—

Fraction 1 was suspected to contain cineol. On shaking with a 50% aqueous solution of resorcinol the absorption was 15–16%. The resulting oil had

$$a_D^{28} = 28{\cdot}25°, \quad n_D^{28} = 1{\cdot}4650, \quad d_4^{30}\ 0{\cdot}8532.$$

These constants agree to some extent with those of sabinene, but an attempt to prepare the solid glycol $C_{10}H_{16}(OH)_2$ was not successful.

Fraction 2 consists almost entirely of terpineol, as shown by the constants, by the odour, and the melting point of the compound with hydriodic acid prepared in the usual manner.

The composition of the oil from the Malabar cardamoms of Travancore, indicated by this work, does not differ from that described by other authors. Mysore cardamom oil also gives similar results. Unfortunately, the wild cardamoms were not available in sufficient quantity for complete analysis of the oil.

Summary.

1. The oil from wild cardamoms gives an abnormally high ester value.
2. The Malabar cardamom oil contains borneol, terpineol, cineol, and sabinene (?), together with esters of acetic acid and another acid (mol. wt. = 182?) having an odour of cumic aldehyde.
3. The Malabar and Mysore oils contain the same constituents.
4. The constants of the Malabar and Mysore oils, most noticeably the refractive indices, alter appreciably on storage.

THE TECHNOLOGY OF CANNING.*

BY OSMAN JONES, F.I.C.

In the year 1810 M. Appert succeeded in nning a prize of 12,000f. offered by the French vernment for the invention of the best method of eserving fruits, vegetables, and the like. In 09 an English tin-plate worker took out a patent a vessel of tin-plate for the preservation of foods. America the canning industry was started in 0 by Underwood and Mitchell, who packed certain its, and also by Daggett and Kensit of New York, o canned salmon and other fish. The canning lustry proper may be said to have started in gland about 1900; prior to this time it had been ried on in a small way. A great impetus was given the industry by the war. America has always the way, and many of her methods and much of ingenious machinery have been adopted in this ntry.

In a factory with a considerable turnover the tin can is usually manufactured on the premises. The -plate must be carefully selected and should possess uniform coating of tin, the thickness of which, thin reasonable limits, is not of undue importance far as meat products are concerned; a suitable ecification for preserving containers in 0·75 gram r sq. dm. A research by the technical staff of National Canners' Assoc. (U.S.A.) has shown that the case of acid fruits the thickness of the tin ating on the plate has a considerable bearing on perforation of the plate; in general, the thicker coating the less liable is the container to perfora- n. Further research is being carried out to ertain what bearing, if any, the method of manu- ture of the steel plate has upon the quality of tin.

It is not possible to obtain tin-plate with an solutely uniform coating of tin. So far as meat oducts are concerned, the quality of the tin-plate as an important bearing upon the appearance and quality of the finished article. It should be free rom pinholes, and entirely covered with tin, because f the meaty matter comes into contact with iron luring the process of cooking, discoloration will ake place. A suitable test for the plate is as follows: A few sheets of tin-plate are selected at random rom each consignment, and are flooded with an lmost cold 3% solution of potassium ferricyanide ontaining about 10% of gelatin. If blue spots of errous ferricyanide develop in the gelatin, the onsignment is rejected as unsuitable. The size of he spots gives no true indication of the dimensions f the surface of the iron which has been improperly oated with tin.

Cans are usually of two kinds: (1) the "sanitary" or solderless can; (2) the hole-and-cap can. The former kind is coming into almost universal use where possible; it possesses the advantage that it is not soldered on the inside joints, and therefore no solder or flux can come into contact with the food material, and also it is more economical to handle in the factory. The hole-and-cap can is usually soldered in most of its joints, the lid being soldered on after the can has received its contents. A small hole is left in the centre of the lid for the escape of gases during the preliminary process of cooking. On the underside of the lid, immediately beneath the hole, a small disc of metal is soldered; this acts as a screen to prevent, as far as possible, any solder coming in contact with the food by dropping through the hole during the final process of sealing. Some manufacturers prefer this variety or can, since the food is partially cooked before the can is finally sealed, some of the gaseous products produced by cooking escape, and it is possible to obtain a more perfect exhaust. The author has experience of both kinds of container, and, in his opinion, the sanitary can is more suitable in the majority of cases

In making the sanitary can, the body is cut out to size and the piece of plate passes to the body maker, where it is turned into shape, and a single flange stamped upon it. It then passes through the soldering bath, where a thin film of solder is run on the outside of the joint. This is the only place where solder is used in the manufacture of this type of can, and then only on the outside. The lids and bottoms are stamped out on a separate machine, and a very small quantity of sealing fluid is auto- matically run into the outer flange; the bottoms and lids then pass to the drying stove, where all the solvent of the sealing fluid is driven off. The bottoms are attached to the body by means of a double seam, the edge of the body resting on the small cushion of rubber formed by the evaporation of the sealing fluid. In this way a perfectly airtight joint is pro- duced. Special attention must be given to this joint; if satisfactorily made it should be U-shaped. In order to test whether the can is sound, it is mechanically filled with compressed air and passed under water; if it be a "leaker," air bubbles are seen to escape, in which event the can is rejected. The lid is, of course, not placed upon the can until it has been filled.

Great care is necessary in the selection of the sealing fluid. It should consist of a solution of rubber in a light solvent such as benzene, b.p. 70°–90° C. If the solvent used has a boiling point above 100° it may not be entirely volatilised in the drying oven, and as a consequence is liable to contaminate the contents of the can. Even a minute trace of this solvent imparts a most disagreeable flavour to the

* Read at a meeting of the Bristol Section on Jan. 3, 1924.

food, and the unpleasant "tinny" flavour of some tinned goods may occasionally be traced to this cause. The cans should be passed through a washing machine before being filled.

The lay-out of a canning factory must depend to a large extent upon the kind of articles to be handled, but in all cases the factory should be so constructed that it can be kept scrupulously clean, and that raw material can be dealt with rapidly after its receipt.

For the production of tinned meats the following departments are required :—

(1) Slaughter department.
(2) Cooling room and curing cellars.
(3) Kitchen where the blanching and preparation of the meats is carried out.
(4) Exhausting, retorting, and cooling.
(5) Lacquering, labelling, packing, and despatching.
(6) The laboratory.
(7) Can-making department, in some factories.

In the kitchen preparation of soup stocks, boning and cutting of meats, and the filling of the cans are the chief processes conducted. The importance of the use of fresh and clean material cannot be too strongly emphasised. Many of the difficulties of the manufacturer are brought about through the lack of sanitary methods in the handling of the articles that are to be turned into food. The greater the bacterial contamination of the article, the more difficult it becomes to put up from it a satisfactory and sterile product.

The filled tin is conveyed by automatic means from the kitchen. Its contents are hot, the temperature depending to some extent upon the nature of the article, but as a rule the nearer to boiling point the better. In order that the space between the contents and the lid shall contain as little air as possible, the can is passed through a machine which gives a single turn to the flange on the body and the flange on the lid ; the lid is now held fast to the can, but an air-tight joint has not been made. The can then proceeds through the exhaust chamber, which consists of a slowly-moving endless belt passing through a steam-heated area. By this means the contents of the can are brought to as near the boiling point as possible. At this stage the can has the lid finally sealed by means of machinery, and is now ready for the cooking or processing, whereby sterilisation is effected. A hole-and-cap can is filled in the kitchen and the lid soldered on. It is then exhausted by a partial cooking in the retorts, taken out, sealed, and again retorted for its final process. In some canneries the exhaust is brought about by passing the cans into a vacuum plant, the lid being sealed on the can during the time that it is under reduced pressure. Such a method is applicable to sanitary cans only.

The operation of exhausting is of considerable importance ; an imperfect exhaust will tend to produce discoloration, and will materially assist decomposition by enabling aerobic bacteria to multiply. Finally, a faulty exhaust will prevent the tin showing a good collapse when cool so that it might be mistaken for a blown tin.

It is now the custom in the trade to mark the lid of every can with a private code, which shows the date of manufacture, and the nature of the contents of the can, so that every separate lot put up can be traced and identified.

Retorting.—This is one of the most important steps in the manufacture, and upon it depends to a large extent the quality of the finished article, and also its keeping properties.

The retort consists of a direct-steam-heated vessel, the steam entering at the bottom. It is usually circular in form, but may be rectangular. In either case the tins are loaded on to trays which fit the retort. It is then filled, the lid screwed down, and the steam turned on. Each retort is fitted with at least one thermometer and a steam-pressure gauge. The temperature is raised to the required point, and maintained for the necessary length of time to bring about the desired result. The regulation of the temperature is usually effected by means of an automatic pressure control on the steam supply pipe.

In some American canneries continuous cookers are used. In this type of machine the cans pass through a steam-heated chamber and receive gentle agitation during their passage. It is claimed by the makers that the use of the continuous cooker reduces the time of cooking. The length of time of cooking can be regulated by altering the rate of the travelling belt with which the retort is fitted.

Immediately the process is completed the tins are cooled below the cooking point, to about 60° C. A lower temperature than this is not desirable, as the tins should be warm for lacquering. The cooling is brought about in one of the following ways : either the retort is flooded with cold water, or the trays of tins are removed and placed under a cold water spray, or immersed in a tank of cold water. The tin is then lacquered—an operation which, in large factories, is carried out mechanically—and labelled and packed for despatch.

The laboratory.—Here are carried out the usual routine examinations of all the raw food materials, and also the tin-plate, solder, flux, sealing fluid, etc., used in the manufacture of the can. To ascertain that the finished article is in a sterile condition before release to the public, sample cans drawn from each batch manufactured are treated as follows : A fair proportion, say 10% of the batch, is placed in a chamber, the temperature of which is maintained at 37°—40° C. for at least 14 days, and the number of "blowers," if any, is noted. Further sample cans are tested for sterility by incubating for at least 8 days at 37° C., by which time any spores which may be present will have probably germinated. No hard and fast rule can, however, be laid down, as it has recently been shown that the spores of *B. botulinus* can remain dormant for a period of 400 days, and probably longer. After incubation the top of the tin is sterilised by burning upon it some methylated spirit or by heating it with a Bunsen flame, the lid is pierced with a sterile awl through the flame, and the awl quickly withdrawn before the flame is removed, thus preventing a rush of unsterile air into the tin. A sterile platinum needle is then inserted

into the contents of the can, and a loopful of the material placed in a tube of sterile culture medium, such as nutrient broth, which is incubated for 48 hours at 37° C., and its appearance noted. If the familiar turbidity indicating non-sterility is noted, it is sometimes desirable to make a bacteriological examination with a view to trace the cause of the trouble.

Heat penetration.—One of the difficulties that the ner has to overcome is to render his products rile without overcooking them. The length of cooking process depends largely upon two factors he period required for the heat to penetrate to centre of the contents of the can, and the thermal th point of the bacteria with which the food erial is likely to be contaminated. The shorter time and the lower the temperature at which possible to process, the better will be the quality the finished article, always bearing in mind the important factors mentioned above. To deter- e the rate of heat penetration, a thermo-couple y be fixed in the centre of the can and connected h a recording instrument through the lid of an oclave. The temperature of the autoclave is d as quickly as possible to the agreed point and time required for the centre of the contents of can to reach this temperature carefully recorded. result is then plotted in the form of a curve. ther method is to fix the bulb of an accurate rmometer in the centre of the contents of the n, make an air-tight joint through the lid of the n and also through the lid of the autoclave, raise e temperature of the latter as rapidly as possible, d again record the readings. The second method ntioned is more troublesome to manipulate but es equally reliable results.

The determination of heat penetration becomes re difficult when the contents consist of a mixture large particles of solid matter in a liquid, such as at and vegetable rations. Under these circum- nces it is best to fix the thermo-couple in the ntre of the largest portion of solids present, and arrange the contents of the can that this large ece of solid is itself in the centre of the can. The eat penetration can then be determined in the sual manner.

The type of bacteria likely to be encountered aries considerably, and the different classes possess lifferent thermal death points. The thermal death oint depends upon the nature of the organism itself nd on the kind of material in which it is existing. s a general rule sporulating species are the most esistant to heat; the spores require either a higher emperature or the same temperature for a con- iderably greater period than do the living organisms n order to reach their thermal death point.

Meyer has shown that the spores of *B. botulinus* ossess thermal death points as follows :—4 minutes t 120°, 10 minutes at 115°, 33 minutes at 110°, 00 minutes at 105°, 330 minutes at 100° C. Bigelow as stated that sporulating organisms will not grow n acid media, such as tinned tomatoes, and that a emperature of 100° for a short period is sufficient o destroy spores in tomatoes and acid fruits. It is, therefore, unnecessary to process these articles at such a high temperature, or for such an extended period as that employed for meat products which are not highly acid in reaction.

Provided the exhaust has been properly carried out, the presence of true aerobes in the finished article is not of such importance, as they will not readily develop in the absence of atmospheric oxygen.

Among the organisms which are sometimes the cause of spoilage unless removed by sterilisation, are the thermophilic bacteria which grow at a temperature of about 33°–55° C. If present in a can which is stored in a hot place they will ultimately develop.

It is quite possible for a can to remain in a fresh condition although not sterile, conditions such as acidity prevent development of the organisms, or the can may be stored at a low temperature which will not favour the growth of thermophilic bacteria. A canner should, of course, endeavour to render all his pack sterile, and in any case must make certain that the articles does not contain spores of any anaerobic bacteria.

It is not practicable to make a bacteriological examination of every consignment and variety of raw material, and as some sporulating organisms possess a heat resistance at least equal to that of *B. botulinus*, the meat canner has perforce to work to high temperatures, or use a prolonged process to ensure producing an article that will keep for an indefinite period.

For example, suppose in working with a temperature of 100° C. that it required 60 minutes for the heat to penetrate to the centre of the can so that it reached boiling point, then to ensure sterility the can would have to be maintained at this temperature for an additional 330 minutes. With higher temperatures the length of time required decreases. The temperature at which sterilisation is effected depends on the nature of the article and on the species of the organisms present, but it is seldom practicable to work with such a low temperature as 100° C., although in some cases it may be necessary. The author's own experience is that in arriving at the necessary process for any particular material, it is always desirable to maintain the temperature for at least an extra 10 minutes beyond the time found for the heat penetration. This extra period may be regarded as a margin of safety.

It is sometimes necessary to determine the amount of vacuum in a can. For this purpose an instrument, the invention of which is due to Young, is employed, consisting of a small vacuum gauge fitted with a perforated pin and a heavy rubber gasket. The can is punctured by forcing the pin through the end, and the vacuum registered on the gauge is noted.

To examine a can which is proved to be unsterile for anaerobic bacteria the method of Novy may be used. This depends upon the cultivation of bacteria in a vessel containing alkaline pyrogallol.

The absence of a blown appearance of the tin does not necessarily indicate sterility; certain kinds of

bacteria do not generate sufficient gas to cause the tin to bulge, and sometimes the tin may contain a small hole which will allow the gas generated to escape. The fact, therefore, that a batch of tins may pass an incubation test satisfactorily does not necessarily mean that they are fit for shipment, and a laboratory examination is essential.

Discoloration.—Meat products which contain spices are very liable to discoloration in the presence of iron. This may to some extent be attributed to the fact that spices always contain tannin, which combines with the iron to form iron tannate. Copper is also frequently the cause of discoloration, particularly in the presence of sulphur compounds, when copper sulphide may be formed. The use of imperfect tin plate is, therefore, to be carefully avoided, as should the food come in contact with iron, discoloration is almost certain to occur. The author has also met cases where discoloration has taken place through the use of copper cooking pots. A third metal which causes this kind of trouble is lead; this is not likely to be present in canned food, but is sometimes met with in the hole-and-cap can through the use of solder.

Metallic contamination.—It is occasionally necessary to examine the contents of a can for lead and zinc, both of which may be present through the use of solder on the inside of a can, and a zinc salt as a flux. For this purpose the methods recommended by Leach in "Food Inspection and Analysis" are satisfactory.

Tin is always present to some extent in the contents of a can, and the author has never yet examined one without finding at least a trace. The tin is usually present as an insoluble salt, and the amount found is higher in the drained solids than in the liquor, although some cases have been known where all the tin present has been in solution. The reaction between the foodstuff and the tin seems to take place most rapidly during the time of processing or cooking, that is when the highest temperatures are reached, and in the case of meat products it seems almost to cease after about four months. The following figures, obtained with a 1 lb. tin of brawn, will make this clear:—

After 48 hours	0·001% Sn
,, 7 days	0·001% ,,
,, 28 ,,	0·0012% ,,
,, 84 ,,	0·0017% ,,
,, 168 ,,	0·0019% ,,
,, 2 years	0·0021% ,,

So far as can be ascertained there is little or no direct evidence that the small amount of tin salts usually found in the food contents of a can can be regarded as poisonous The danger, therefore, that arises from this cause may be regarded as negligible.

THE DETERMINATION OF ACETIC AND BUTYRIC ACIDS.*

BY ERNEST FYLEMAN, B.SC., PH.D., F.I.C.

It is usual in the examination of fermentation products to distil the volatile acids after acidification with sulphuric or phosphoric acid; the total acidity of the liquid so obtained is then found by titration with standard alkali, using phenolphthalein as an indicator. The acetic acid in such products is generally accompanied by a certain quantity of butyric acid, the determination of which by ordinary methods is difficult. The determination of the equivalent weight by means of the barium or silver salts does not give satisfactory results as neutral barium salts decompose, possibly by hydrolysis, on evaporation of the solution, and the silver salts deposit metallic silver under such conditions.

It has been found that butyric acid can be determined in such liquids with a considerable degree of accuracy by boiling with excess of potassium dichromate in a sulphuric acid solution of definite strength. Under such conditions butyric acid is oxidised to acetic acid and carbon dioxide, and reduces the dichromate to the extent of the equivalent of 6 atoms of oxygen. Propionic acid acts similarly, exercising a reducing action equivalent to 3 atoms of oxygen, whilst acetic acid remains almost unattacked. A correction is necessary for the reducing action of the acetic acid, whether originally present or produced by the oxidation of its homologues.

The distillate containing volatile acids is titrated as usual with $N/4$ sodium hydroxide in the presence of a minimum quantity (2 drops) of alcoholic phenolphthalein solution of the usual concentration. It is then boiled down to half bulk in order completely to remove the alcohol from the phenolphthalein solution, and subsequently diluted to such an extent that 20 c.c. of the liquid correspond to approximately 1 c.c. of $N/4$ sodium hydroxide solution.

To 20 c.c. of the liquid 25 c.c. of $N/4$ potassium dichromate solution are added in a conical flask of about 300 c.c. capacity, which is placed under a reflux Liebig condenser; 30 c.c. of concentrated sulphuric acid (96%) are then added through the condenser, with shaking, and the liquid is at once boiled for exactly one hour. It is then cooled, diluted to about 250 c.c. and titrated with $N/4$ thiosulphate solution after addition of potassium iodide, finally using starch paste as an indicator.

As the reducing action of butyric acid is equal to 6 atoms of oxygen, then—apart from the correction for acetic acid—each cubic centimetre of $N/4$ dichromate solution (equivalent to 8 grams of available oxygen per litre) represents $88 \div (6 \times 8000) = 0{\cdot}00183$ g. of butyric acid. Should propionic acid be present this cannot, of course, be distinguished from butyric acid by this method, but as the oxygen absorption is proportional to the increased weight of organic acids, the total weight of organic acids is correctly determined, a matter of technical importance, though a portion of the "butyric acid" found may, in reality, consist of an equimolecular mixture of acetic and propionic acids. As the greater part of the oxidation to acetic acid takes place in a very few minutes, the correction for the reducing action of that acid may without appreciable error be based on the number of molecules of organic acid originally present—that is, on the total acidity; if n is the number of c.c. of $N/4$ sodium hydroxide required to neutralise the quantity of organic acids used in the

* Read at a meeting of the London Section on Jan. 7, 1924.

etermination, this correction is equal to 0·5n. hus, the weight of butyric acid present is equal to ·00183(b—0·5n) where b is the number of cubic entimetres of N/4 dichromate which are reduced. his will be clear from the following numerical esults :—

Acetic acid, g.	Butyric acid, g.	Equivalent c.c. of N/4 NaOH (=n).	C.c. N/4 $K_2Cr_2O_7$ reduced (=b).	Butyric acid calc (g.) = 0·00183 (b-0·5n).
Nil	0·0218	1·0	12·2	0·0222
0·02	Nil	1·3	0·7	Nil
0·01	0·0109	1·15	6·6	0·0110

In the case of propionic acid the equation is :— ght of propionic acid=74(b—0·5n) ÷ (3×8000)= 308(b—0·5n). The following numerical result was ained with this acid. Propionic acid present, g. Equivalent of N/4 NaOH 1·08 c.c., N/4 r_2O_7 7·1 c.c. Propionic acid calculated=0·00308 0·5n)=0·00308(7·1—0·54)=0·0202 g.

few experiments were carried out to investigate effect of variations in the quantity of sulphuric . Using 0·218 g. of butyric acid with 30 c.c. of phuric acid the volume of dichromate reduced 12·2 c.c., with 28 c.c. of acid 11·7 c.c., and with c.c. 13·1 c.c.

The result of reducing the duration of boiling 1 hour to ½ hour was to decrease the volume dichromate reduced from 12·2 c.c. to 11·75 c.c. he method has proved entirely satisfactory in ual practice.

The author is indebted to Mr. H. Langwell and to ssrs. Power Spirits, Ltd., in whose laboratories the ork was carried out, for their kind permission to ublish these results.

COMPARATIVE STUDY OF SOME COAL ARS PRODUCED BY LOW-TEMPERATURE CARBONISATION.*

BY K. B. EDWARDS, PH.D., LOND.

(*From the Cooper Technical Bureau.*)

This paper contains a record of an investigation of al tars produced by low-temperature carbonisation, ommenced by the author in 1920. An extensive echnical acquaintance with products from blast-urnace tar and also comparative examinations of roducts from vertical-retort tars and such tars as ould be obtained from specific low-temperature arbonisation processes, had led the author to the onclusion that all these tars conformed to one type, nd their values were substantially equal and, there-ore, low owing to their unknown character. This iew has received a certain amount of confirmation n recent years.

The utilisation of blast-furnace tar has advanced very little during the last 35 years. Direct distillation at atmospheric pressure gives blast-furnace creosote, a greenish-brown oil of low viscosity, d 0·950–0·980, b.p. 200°–325°, phenolic content 20—35%, with blast-furnace pitch of rather paraffinoid character.

* An abridgment of a thesis submitted for the Ph.D. degree of London University.

Until about 1912 blast-furnace creosote was of very low value, ranging from ½d. to 2½d. per gallon. The increase in value since 1905 is due to the more general use of the creosote as an oil fuel and of the phenol fraction (b.p. 215°–300°) for the production of disinfectants.

The process consists of extracting the creosote with caustic soda solution (about 10%), carbonating the alkali phenolate, and fractionating the separated phenols. The fractions obtained are usually three in number, viz., cresylic acid, b.p. 195°–210°; intermediate acid, 205°–220°; high-boiling acid, 215°–310°. The first two fractions are of relatively low value, and only the high acid yield renders the process profitable. The neutral oils and basic constituents are fit only for fuel, the oils being unsaturated, and the bases unsaleable at any remunerative figure The value of the high-boiling tar acids has been due to the fact that blast-furnace creosote has been the only available source, but no use is known for them except in the manufacture of disinfectants.

Résumé of published literature.

The literature on the subject of blast-furnace tar is extremely scanty. Watson Smith and his co-workers noted the decomposition of blast-furnace tar during distillation, and found in the distillate traces of phenol and the cresols and indications of xylenols, pseudo-cumenols, and possibly naphthols. Their conclusions generally were against any great technical value in these tars. Allen and Angus claimed the phenols to contain methoxyphenols, guaiacol and its homologues, and these statements are still copied into recent literature.

On low-temperature tar much work has been published in the last 20 years, much of which is polemical and of low scientific value, but the work of Bornstein, Jones and Wheeler, Maclaurin, Tideswell and Wheeler, Fischer and his co-workers, Marcusson, and Morgan and Soule, is outstanding. The results of Pictet and his co-workers on vacuum tars do not conform to the results found elsewhere. The observations of Maclaurin are of great interest, and the author has followed up his work and confirmed the main peculiarities noted by him. The published work up to June, 1923, may be summarised as follows :—

Low-temperature tar when subjected to ordinary distillation yields : Pitch, of poor brittle quality. Neutral oil or hydrocarbons, consisting of unsaturated hydrocarbons, paraffins, naphthenes, and probably smaller quantities of aromatic hydrocarbons with traces of methylnaphthalenes. Phenols, consisting of cresols, xylenols, and trimethylphenols with higher phenols of unknown constitution. Nitrogenous bases, mainly secondary and tertiary bases of unknown constitution, with possibly traces of primary bases. Appreciable quantities of phenol, benzene, and toluene are not found by the majority of the workers. The results of Pictet and his co-workers appear to stand alone, and to require further investigation. The presence of oxygenated compounds in the hydrocarbon portion is highly probable, and the presence of pyrocatechol and other dihydric phenols

in perceptible quantities is reported by several observers.

Beyond the technical treatment of these tars on the known lines of blast-furnace tar little advance appears to have been made.

Low-temperature tar dealt with in other ways not involving ordinary distillation yields: Petroleum-soluble portion, alkali-soluble portion, part phenols, part resin; resins precipitated with mineral acids (Maclaurin); tar resins (Marcusson); pyrocatechol (Börnstein, Fischer, and others); orange-red lubricating oils (Fischer and others); phenols, as in ordinary distillation. The presence of acids, alcohols, and ketones is in doubt. No attempt has apparently been made to effect a clean separation of various groups of substances present, and in the opinion of the author, until this is done, little is gained by ascertaining the presence of unimportant traces of various constituents.

All evidence tends to show that the valuable aromatic products present in high-temperature tar are absent in low-temperature products. In addition, crude products such as cresylic creosote, salty creosote, and green (anthracene) oil, which form the main bulk of the distillate from high-temperature tars, will either be absent or degraded to such an extent as to be of much lower value. Examination by the author of products from tars produced in America and the colonies shows that unintentional low-temperature distillation of coal in continuous vertical retorts is producing tars closely resembling blast-furnace tar, with all its undesirable characteristics. The pitch also tends to be brittle and of low value.

Investigation of four typical low-temperature tars.

The author has made a comparative examination of the tars produced by different processes, representative samples of the following tars having been obtained, by the courtesy of the various organisations: (1) Blast-furnace tar; (2) "Coalite" tar; (3) Scottish by-products tar (Maclaurin process); (4) Dundee gas tar.

These four tars were chosen for the following reasons. Blast-furnace tar was considered to be the prototype of low-temperature tars. "Coalite" and Maclaurin tars were produced by two different established methods of low-temperature carbonisation, while Dundee gas works tar was known to be an outstanding example of an "unintentional" low temperature tar, being produced from semi-bituminous Scottish coals in continuous vertical retorts. The blast furnace tar was produced from splint and hard Scottish coal, the "Coalite" tar from a mixture of coking and non-coking Barnsley-district coal, and the Scottish by-product tar from Scottish coking coals.

I. EXAMINATION BY DISTILLATION.

The four tars, blast-furnace (B), "Coalite" (C), Scottish by-products (S), and Dundee gas tar (D), are referred to throughout this work under the letters placed in parenthesis.

Character of the tars.—Tar S was extremely viscous but fairly clean; B was viscous and opaque, and obviously contained solid matter in suspension; D was much less viscous, and C slightly less viscous, the last two being very similar in character.

The specific gravities at 15° C. were: B, 1·151, C, 1·081; S, 1·048; D, 1·115. The tars were freed from water as much as possible before the gravities were taken. When 5 c.c. of the tar were shaken with 10 c.c. of hot distilled water and allowed to settle, the supernatant water from tars B and D gave an alkaline reaction, that from S was neutral, and that from C distinctly acid.

Distillation at atmospheric pressure.—Throughou the work the conditions were kept as uniform a possible. All temperatures were corrected and thermometers checked frequently.

Preliminary tests showed that distillation, carrie to completion (*i.e.*, to incipient coking) at a fi temperature of about 375°, left in the still pitche about 28–35% of the original tar, and so brittle they were technically useless. As it was desir keep within the limits of technical practice, distillation was finished when the thermometer the vapour outlet touched 311°. These prelimina tests were carried out on 500 c.c. of tar in a 1-lit Wurtz flask with the thermometer bulb at the lev of the side tube.

Tars B and C distilled quietly, tars S and D froth and bumped badly. Neither the viscosity n water content would serve as a guide to the lil of frothing, for the viscosity was in the a order C, D, S, B, and the water content in t r B, D, C, S.

During the distillation tar C gave off ulp dioxide, and later hydrogen sulphide and hyd ch acid, but no ammonia. Tar B gave ammor , t of hydrogen sulphide and, in the later sta s, hy cyanic acid. Tar D gave mainly ammonia, wit hydrogen sulphide, while S yielded hydrogen sulphide Tars C and S gave in the condenser and flask trace of sublimed yellow solid material, resembling sulphu but which decomposed with effervescence on fu er heating.

The distillate was collected in one vessel and s r ated from water. The aqueous portion was tinctly acid in the case of tar C and alkaline (ammon from B, D, and S. C resembles in this respe vacuum tars obtained by Pictet and Bouvier, a also those of Jones and Wheeler. The whole distilla in each case was then treated as follow, to ascerta the content of phenols and bases.

Phenols.—The distillate was extracted twice wit an equal volume of hot sodium hydroxide solutio (*d* 1·15), the temperature of the mixture being raise to 50°–60°. A third extraction with concentrate soda solution (*d* 1·45) was found to be unnecessary The alkaline washings were united, allowed to separat from any traces of oils, and subjected to steam distillation until the distillate contained no traces of oils or bases. The distillate containing traces of oils and bases was mixed with 50% of its volume of concentrated hydrochloric acid and used for the extraction of the bases from the oils. The purified alkali phenolate solution, which remained quite clear when diluted with water, was cooled and acidified with hydrochloric

cid, the liberated phenols collected, the acid liquor xtracted with ether, the extract dried over anhydrous odium sulphate, the ether removed at as low a temerature as possible, and the phenols measured.

Bases.—The acidified distillate mentioned above as thoroughly shaken with the washed residue, rom which phenols had been removed and separated fter standing. A final washing with concentrated ydrochloric acid was given, and the acid washings ere united, freed from neutral oil, made alkaline vith 40% sodium hydroxide solution and extracted hree times with ether. The united ether extracts vere dried with solid potassium hydroxide, the ether emoved and, on account of their small volume, the ases were weighed.

During the extraction of the phenols it was found hat the alkaline solution of the phenols on contact with ir gave rise to the crimson colour which is a notable haracteristic of the creosotes from most tars of this ype. The intensity of colour varies with different rs, and in the four under examination D and S ve intense colours, while B was of medium intensity, d C gave very little colour for a low-temperature r. This coloration is looked upon as a grave fect in the use of creosotes in disinfectant manucture, but definite identification of the constituent hich gives rise to the colour has not yet been posble. The following facts, however, are known. The colour-forming substance has a high-boiling point, and tends to concentrate in the higher fractions. It is definitely phenolic in character, being insoluble in alkali carbonate solutions, but soluble in weak caustic alkali. It is a relatively highly acidic phenol, and is precipitated among the last portions of the phenols if acidification is carried out in stages. In the presence of alkali it is oxidised first to the crimson colour and then to a brown, but is stable in neutral or acid solutions. Sunlight materially assists the oxidising process. While many guesses have been made as to the type of phenol producing this effect, the presence of polyhydric phenols being the usual explanation, the author considers that, in the absence of actual isolation of the pure substance, the characters are more those of a leuco-derivative of a condensed phenol compound similar to rosolic acid or aurin. The substance is certainly not either of these, but the indications are that it is of that type, or even more of the type of the coumaranones.

The results obtained in the foregoing examination can best be summarised in the following table :—

TABLE I.

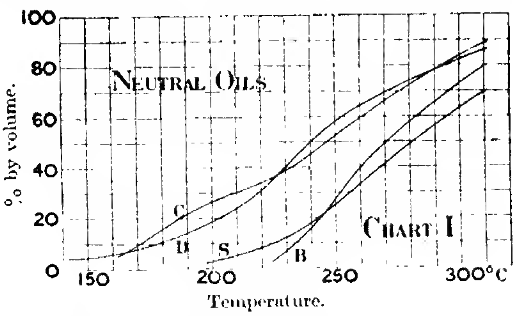
	Blast-furnace tar B. %	Coalite, tar C. %	Dundee gas tar D. %	Scottish by-product tar S. %
Sp. gr. of tar at 15°/15°	1·151	1·081	1·115	1·048
Pitch at 311° by vol	56·6	50·4	62·5	53·0
Water by vol	0·2	5·4	1·5	11·0
Sp. gr. of distillate	0·980	0·968	0·993	0·982
Phenols on distillate by vol.	34·3	33·3	30·0	37·2
Phenols on tar—by vol.	14·6	15·0	10·8	13·4
Bases on distillate, wt./vol.	5·8	2·9	4·4	3·6
Bases on tar, wt./vol.	2·5	1·3	1·6	1·3
Character of pitch	Paraffinoid, mediumly hard.	Very brittle.	Hard and brittle.	Very paraffinoid—soft.

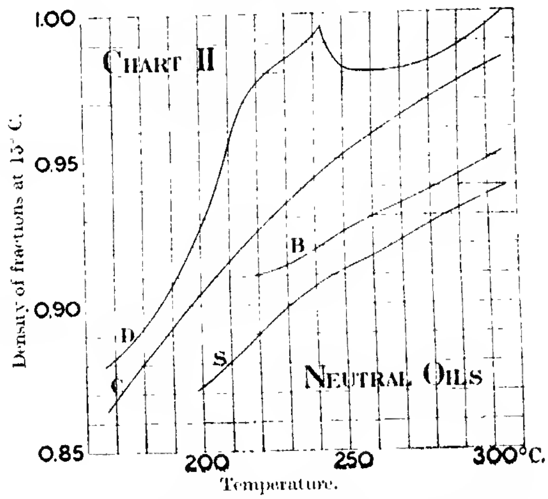
It will be seen that the specific gravities of three of the tars (B, C, and D) fall outside the limits given by Fischer and Glund of 0·95 to 1·06. The results given in the Report of the Fuel Research Board (Beilby, 1922) show that the type of coal carbonised affects the gravity of the tar, different coals carbonised at 600°, giving tars varying in sp. gr. from 1·030 to 1·063. Other factors also probably come into the matter, and specific gravity alone is certainly not a safe guide in determining whether or not a tar is a true low-temperature product.

The yield of pitch is considerably higher than could have been attained by forcing distillation further, but even at 311° the pitches C and D were brittle and poor, while B and S were paraffinoid and of low value. The specific gravity of the distillate is much more uniform than that of the tars, and the phenolic and basic content are closely similar.

In order to obtain sufficient material to work upon, the preliminary distillation was repeated, working upon 2 litres of each tar. The tar was distilled in short-necked round-bottomed 3-litre flasks of uniform dimensions and again uniformity of treatment was attempted as far as possible. The distillate was separated into neutral oils, phenols and bases and each of these was treated as follows.

Neutral oils.—The washed neutral oils were fractionated through a four-pear Young column at the





rate of approximately 2 drops per second, the fractions obtained every 10° being kept separate The results are shown in Charts 1 and 2. Chart 1

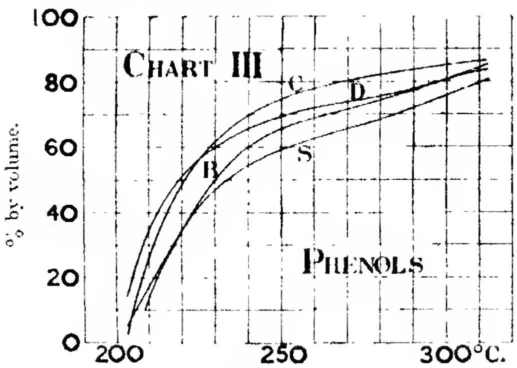
gives the cumulative volume-percentage of the whole, boiling below the indicated temperature, and Chart 2 the sp. gr. of each fraction plotted against the mean boiling point.

The fractionation proceeded normally with the oils from tars B, C, and S. The oil from tar D, however, showed the presence of naphthalene in the fractions between 200° and 250°. The presence of naphthalene is indicated clearly in curve D, Chart 1, by the depression of the volume boiling below 200° and the sharp rise at 215°. The effect is enhanced enormously in Chart 2, where the specific gravities of the fractions of oil D are very considerably increased between the temperatures 200°–270°. Tar D is obviously aberrant and is a mixed product, a relatively small proportion of high-temperature products being imposed on a large proportion of true low-temperature products. A small quantity of crystalline matter obtained from the higher-boiling fraction of oil D consisted as far as could be ascertained of anthracene and phenanthrene. Oils C, B, and S gave smooth curves, and in the author's opinion, clearly demonstrate that, other than for fuel purposes, nothing can be hoped for in the technical treatment of oils of this nature.

Examination of the oils confirmed the presence of paraffins, naphthenes, and unsaturated hydrocarbons. In view of the failure to utilise blast-furnace oil produced by distillation, further work has been postponed until all other avenues of approach have been tried.

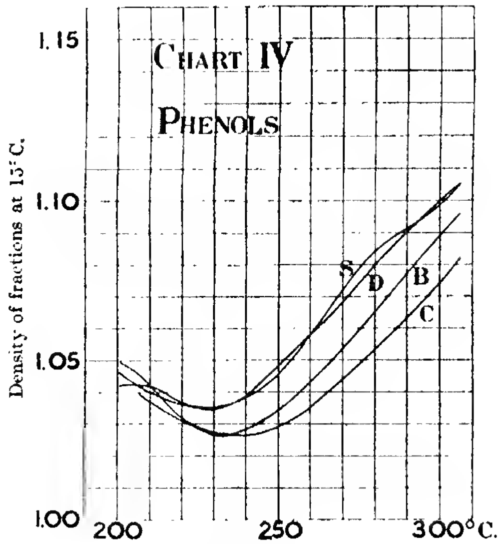
Chart 1 shows clearly that tars B and S have been stripped of their lighter constituents by the excessively large current of gas to which they have both been subjected; also that tar B produces oils very similar to tar S, notwithstanding the difference in sp. gr. of the original tars. Tar C apparently occupies a position midway between D and the others, but is definitely a low-temperature tar.

The oils, although pale yellow to green in colour when freshly distilled, rapidly darkened and were obviously unstable, and no economical means of purifying them could be found.



Temperature.

Phenols.—The carefully dried phenols were fractionated in the same manner and distillations and specific gravity charts were prepared (Charts 3 and 4). Chart 3 shows that there is a very close similarity between all four lots of phenols. Tar D, however, again shows slight signs of high-temperature car-



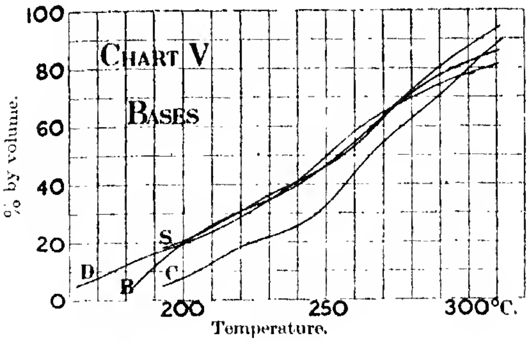
Temperature.

bonisation with a rather higher percentage of cresols and xylenols, while tar C is again intermediate between tar D and the closely allied tars B and S; otherwise the curves are smooth and give little hope that fractionation alone will produce any valuable results.

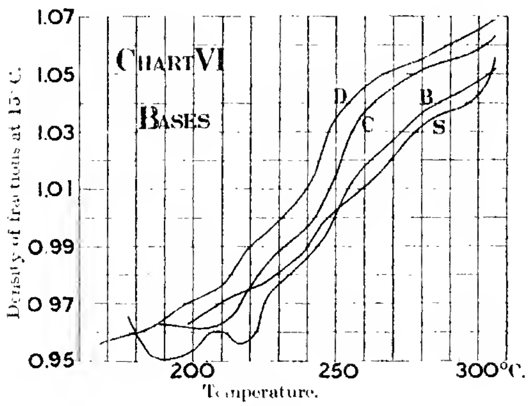
Chart 4 is of extreme interest. The specific gravity of the fractions falls until a temperature of 235° is attained and then rises rapidly. This alone refutes the previously expressed opinion that these tars contained guaiacol and kindred substances. Examination of these curves led to the conclusion that the phenols consisted of monohydric mononuclear phenols mixed with unknown phenolic substances of very high boiling point which possibly decomposed to some small extent during distillation and partly distilled unchanged. These unknown phenols obviously had a high specific gravity; they did not give any noteworthy coloration with ferric chloride, neither did they give the Liebermann reaction. The higher fractions of the phenols were gummy and resinous, and these unknown phenols the author terms "*rhetinols*" for convenience. If the above hypothesis be accepted, the mononuclear phenols should all possess the characteristic "carbolic" odour and taste, and show a gradually falling gravity boiling point curve. During the distillation of the phenols, hydrogen sulphide was given off in all cases, and ferric chloride gave the reactions of pyrocatechol and α- and β-naphthol, but only as being present in traces. The fractions above 230° from al the tars darkened rapidly and obvious decomposition took place at the higher boiling points.

Bases.—The basic constituents were fractionated in an identical manner (Charts 5 and 6). Owing to the small quantity of bases available, the errors

are probably of greater magnitude in this examination than in the case of the oils and phenols. Chart 5 shows that the tar C produces bases of slightly



different boiling point from the tars B, D, and S. The latter are practically identical within experimental error. The curves are all smooth, showing that fractionation alone is of small assistance. Chart 6 shows, however, apparent complexity up to



220°, with slight irregularity round 250°–260°. The quantity of material worked with was too small to permit any definite conclusions and the problem must be attacked on a much larger scale. The close similarity of the four tars is, however, well brought out.

Summing up the foregoing, the following points appeared to be fairly well established:—

1. Tars B, S, and C are all of the same type and contain little or no naphthalene, and generally represent true low-temperature tar as technically produced in Great Britain.
2. Tar D, while showing signs of introduction of high-temperature tar, is very similar in most respects to tars B, S, and C.
3. The phenolic substances of all four tars are substantially identical.
4. The basic constituents are similar.
5. With the exception of naphthalene, in relatively small quantities, in tar D, the whole of the tars produce little of value by direct distillation that has not been available in blast-furnace tar.
6. All the pitches produced are of low value.

The basic hypothesis that low-temperature tars are substantially identical with blast-furnace tar when subjected to ordinary distillation would appear to be proved, and the close similarity of tar D in its main characteristics is also established. Tar D, therefore, is what has been termed an "unintentional" low-temperature tar and will require technical treatment along the same lines. The difference in the percentage of low-boiling oils obtainable is explainable, inasmuch as tars B and S were both produced in a current of hot gas in large volume, while tar C was produced from an experimental plant not fitted with suitable gas-cooling devices.

In view of the above facts it was determined to attack the problem by methods not involving distillation and to carry on the comparative work along these new lines.

II.—Examination by Solvent Extraction.

As it was desired to use a solvent of low cost, volatility, and fire risk, 94% industrial alcohol was employed. The use of alcohol in the treatment of blast-furnace creosote was patented (McDougall and Howles, E.P. 8323, 1912) and a very large scale plant worked under the author's direction was fairly satisfactory as far as solvent cost was concerned.

500 c.c. of the tar were extracted with an equal volume of 94% alcohol, in the cold, with violent agitation. The mixture was allowed to separate and, after separation, the alcoholic layer was poured off and another 500 c.c. of alcohol added, again thoroughly shaken, settled, and poured off. Four extractions appeared to remove practically all soluble matter. After the first extraction with all four tars separation was slow, but the subsequent washings separated easily. The washings from each tar were combined and allowed to stand until clear, when the clear alcoholic solutions were decanted and the residues added to the insoluble matter.

The alcoholic extracts all showed a greenish fluorescence, slight in the cases of tars S, C, and D, while tar B gave an extract which had a strong greenish-yellow fluorescence.

The alcohol was removed from both the extract and the insoluble portion by slow distillation through a 12-pear Young dephlegmator and a sharp "cut" was obtained in all cases; none the less the recovered alcohol showed traces of hydrocarbons, although the quantity was small.

The results obtained can be summarised as follows:

	Tar B. %	Tar C. %	Tar D. %	Tar S. %
Alcohol-soluble material % by vol.	70	64	76	66
Residue	29·8	30·6	22·5	33
Water	0·2	5·4	1·5	11
Sp. gr. extract at 15°/15°	1·060	1·085	1·100	1·075

It will be seen that the specific gravity of the extract bears no relation to that of the original tar. The extracts were deep orange-brown in all cases, while the consistency was thinner and the viscosity was much less than that of the original tars. The viscosity ran in the ascending order, C, D, S, B, but the difference was small.

The insoluble residue contained all the mineral matter in the tar but also much organic matter. On extraction with carbon disulphide the four residues yielded dark, almost dead black substances granular in appearance, on further testing, they were found to be mixtures. The residue insoluble in carbon disulphide contained mineral matter and free carbon and was not examined further. The actual quantities of mineral matter obtained were:—B, 13·0%, C, 4·6%; D, 5·0%; S, 0·6% wt./vol.

Examination of the alcohol extract.

Phenols.—The extracts from which alcohol had been removed were quantitatively examined as to phenol content as already described, with the exception that the purified alkali phenolate solutions were not acidified with mineral acid but were carbonated with carbon dioxide. This course was adopted in order that any carboxylic acid might be separated from the sodium carbonate liquor.

No difficulties arose in this process, but it was notable that very little crimson coloration developed in the alkaline solutions, thus appearing to demonstrate that the material producing the colour is a product of decomposition on distilling the tar. The alkali phenolate solutions frothed strongly and persistently on shaking; this frothing, which has not been noticed before, was accentuated if the phenolates were well diluted, and no apparent hydrolysis took place on dilution. The complete extraction of phenols was assured by allowing the residual oil to stand for 2 or 3 days over stick caustic soda. This was found to add nothing to the already extracted phenols. The alkaline solution was then carbonated with a current of pure washed carbon dioxide until precipitation was complete. The phenols were precipitated as a dark resinous mass and separated, and the carbonate liquor was extracted twice with ether and the ether solution added to the precipitated phenols. As usual, the precipitated phenols contained some soda, and it was found necessary to neutralise with hydrochloric acid before they became workable. The phenolic compounds contained material insoluble in ether, cold alcohol, or alkalis, but soluble in pyridine. This material, which later was found to be present in almost all stages of the extraction, was identified as being similar to Marcusson's "tar resins," and to the materials described under the general term "ulmins," and is so termed throughout this work. The "ulmins" are soluble in many of the tar products, particularly phenols, and still remain in solution in the alkali phenolate solutions, and also in concentrated solutions of the tar products in solvents. The addition of excess of ether or other solvent often precipitated "ulmins." This solute-solvent action is dealt with later, as affecting much of the published work on the action of solvents on tars. The ether solution of phenols was dried, the ether evaporated, and the residue taken as phenols.

Carboxylic acids.—The sodium carbonate liquor from the phenols was made just acid with hydrochloric acid and extracted with ether, the ether dried and evaporated, and the residue redissolved in hot sodium carbonate solution, treated with ether to remove any traces of phenols, reprecipitated, and again taken up in ether, dried, and recovered.

Bases.—The mixture of neutral oils and bases, left after extraction with soda, was treated with dilute hydrochloric acid. The first washing separated well but the second washing precipitated flocculent material, while the third washing gave a semi-solid emulsion which broke up on the addition of ether to a clear top layer, a slightly yellow or orange acid solution, and a large quantity of dark resinous or gummy substances which formed masses on the sides of the separator. This phenomenon was recognised as being similar to that observed by Maclaurin, and was considered (wrongly, as later work will show) to be simply a precipitation of "ulmins" and other materials which had been held in solution by the bases. The clear acid washings were made alkaline and the bases recovered in the usual way.

Hydrocarbons and neutral oil.—The added ether was recovered and the oily residue taken as "neutral oils."

A COMPARATIVE STUDY OF SOME COAL TARS PRODUCED BY LOW-TEMPERATURE CARBONISATION.

BY K. B. EDWARDS, PH.D., (LOND.)

(From the Cooper Technical Bureau.)

(Continued from p. 148 T.)

Acid resin.—This term describes the material precipitated by, but insoluble in, dilute hydrochloric acid. The product was extracted with acetone and left a residue of the "ulmins." The acetone solution, after removal of the acetone, left a dark, sticky, semi-solid mass.

The quantitative comparative results can best be expressed as follows:—

	Tar B.	Tar C.	Tar D.	Tar S
Phenols.	%	%	%	%
Volume % on extract ..	30	38	39	36
Volume % on tar ..	21	23	20	23
Sp. gr. 15°/15°	1·074	1·053	1·093	1·098
Character of phenols ..	Thick, somewhat sticky.	Fairly thin, not sticky.	Thick, very sticky.	Very thick, very sticky.
Neutral oils.				
Volume % on extract ..	47	44	42	40
Volume % on tars ..	33	28	32	26
Sp. gr. 15°/15° ..	1·009	1·036	1·048	1·018
Odour	Pleasant aromatic.	Pleasant aromatic.	Naphthalene like	Pleasant aromatic.
Carboxylic acids.				
Wt./vol % on extract	0·16	0·4	0·32	0·16
Wt./vol. % on tars ..	0·13	0·2	0·22	0·12
Bases.				
Wt./vol. % on extract ..	4·4	2·7	3·1	2·8
Wt./vol. % on tar	3·1	1·7	2·1	1·9*

* This tar gave traces of basic substances insoluble in ether or any other solvent except concentrated hydrochloric acid.

Alcohols were absent in each case.

All the tars are seen to behave similarly, and the presence of "ulmins" (tar resins) and carboxylic acids, detected by Marcusson, is confirmed. The absence of alcohols is also in agreement with most workers, excepting Pictet and his co-workers; nonetheless, the author was by no means satisfied that the various products obtained were homogeneous, and details of further examination of the products are given below.

Phenols.—The phenols obtained from each tar were treated with excess of light petroleum (b.p. 70°–120°). Three volumes of light petroleum were used at each washing and three washings were given, allowing 24 hours' standing after each washing to ensure complete precipitation. The washings were united and allowed to stand, when further precipitation occurred. The clear solution was tested with successive additions of solvent, and, when no further precipitation occurred, the petrol-soluble phenols were extracted with soda and recovered in the usual way. The insoluble phenols were dissolved in ether, when precipitation of "ulmins" took place. The solution was diluted until precipitation ceased, filtered, and the ether distilled off. The petrol-insoluble phenols were then obtained as a solid resinous mass and, after removal of all traces of solvent, set to a brittle solid, with practically no odour or taste. This dissolved in dilute caustic soda to a clear brown solution, showing a remarkable foaming on agitation. This substance was definitely phenolic in character, but gave none of the usual phenolic reactions, and was considered to be the material previously termed "rhetinols" from its resin-like character.

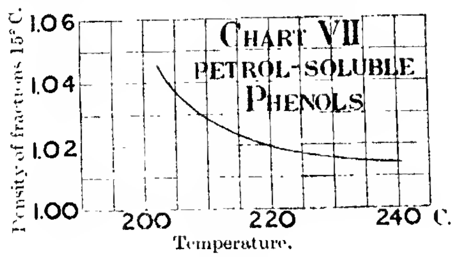
The "ulmins" obtained were of the same type as those previously described.

The petrol-soluble phenols were all thin liquids, without any apparent stickiness. The phenols from the four tars were separately treated, with the following results:—

	Tar B.	Tar C.	Tar D.	Tar S.
	%	%	%	%
Petrol-soluble phenols	51·8	77·6	31·3	46·8
Rhetinols	15·1	20·8	65·8	50·5
Ulmins	3·1	1·6	2·9	2·7
Sp. gr. of petrol-soluble phenols	1·043	1·043	1·059	1·052

It will be seen that the specific gravity of the petrol-soluble phenols has fallen considerably after the removal of the rhetinols, but in view of the experience gained previously, it was considered by no means certain that the whole of the rhetinols was removed. The petrol-soluble fractions were separately distilled, when it was found that, after attaining 260°, the temperature rose rapidly, and the distillation was stopped. The residue in the flask was insoluble in petrol and was identical with the rhetinols previously isolated. The four fractions gave the following amounts of phenols up to 260° (% by volume of petrol-soluble phenols): B, 49%; C, 66·7%; D, 50%; S, 50%.

Owing to the small volume of the phenols and to their apparent identity, the distillates were united and fractionated through a rod and disc column. The distillation proceeded as follows:—Up to 200°, 11%; 205°, 30%; 210°, 42%; 215°, 55%; 220°, 65%; 230°, 75%; 240°, 81%; to 260°, 90%.



The temperature rose rapidly at 250°–260° and still more rhetinols were recovered from the residue in the flask. The fractions were kept separate and a specific gravity/temperature curve drawn (Chart 7). This demonstrates clearly that the hypothesis

stated previously as to the phenols being a mixture of homologues of phenol boiling up to 240°-260° with high-boiling rhetinols is substantially correct. With the removal of the rhetinols of high sp. gr. and b.p. the sp. gr./b p. point curve is a gradually descending one, as would be expected. In view of the small quantity of material available, work on the phenols was suspended and resumed later (*vide infra*).

Neutral oil.—This product also was not homogeneous; treatment by excess of petrol produced a precipitate consisting partly of the ubiquitous "ulmins," and partly of ether-soluble asphaltic material.

The neutral oils were treated with petrol until precipitation ceased (usually about 8 times the volume of oil), the clear petrol solution was decanted, and the solvent distilled off through a 12-pear Young column. The precipitate was then extracted with ether and the ether recovered. The residue was dried *in vacuo* and consisted of "ulmins."

The petrol-soluble oils were all dark red-orange in colour, only slightly soluble in cold alcohol, soluble in hot alcohol, also in ether, carbon tetrachloride, and most solvents. They were highly unsaturated. The sp gr. of the oils was: B, 1·007; C, 1·036; D, 1·045; S, 1·018. The ether-soluble asphalt was obtained in only small quantity as follows: B, 4·4%; C, 3·4%, D, 3·6%, S, 2·2%. This material was very similar to the carbon disulphide-soluble material obtained in the original alcohol extraction and was very dark in colour. Little could be learned of its nature. The "ulmins" were identical with the material previously obtained, and about 3% was obtained from each oil.

The *carboxylic acids* were semi-crystalline, viscous liquids with a low melting point and had an odour resembling that of coconut fatty acids; the quantity was too small for investigation, but they did not resemble humic acid, appearing to resemble naphthenic acid.

Dihydric phenols.—Mixed with the carboxylic acids before purification were perceptible quantities of pyrocatechol. The quantity present was small and could not be definitely ascertained, but was estimated to range from 0·2% to 0·8% of the tar.

Examination of the various asphalt-like materials obtained showed the presence of "ulmins" in all, contaminated with a basic material which was precipitated by hydrochloric acid from benzol solutions, but the salts of which were not soluble in water

Summary of Part II.

Notwithstanding the care taken in the extraction, none of the products, with the exception of the homologues of phenol, could be taken as homogeneous. The figures obtained, while interesting as showing the similarity of the four tars, are not of great value, owing to the impossibility of clean separation, due to the "solute-solvent action" previously referred to. Nevertheless, the following points have been clearly demonstrated:—

(*a*) All four tars contained the brown amorphous powder referred to by Marcusson as "tar resins," and the failure of Tropsch to obtain more than traces of these substances was, in all probability, due to the non-recognition of the solute–solvent factor.

(*b*) The presence of carboxylic acids in all four tars was definitely established, thus confirming the work of Marcusson and Tropsch.

(*c*) The phenolic content of the tars has been divided into two main groups, *i.e.*, homologues of phenol and resinous phenols of high density, practically odourless and tasteless, which have been termed rhetinols, and which are insoluble in light petroleum.

(*d*) The observation of Maclaurin as to precipitation of resinous matter with dilute hydrochloric acid has been confirmed for all four tars, and evidence has been obtained that, when carefully purified, the substance forms salts insoluble in water and benzene but soluble in alcohol.

(*e*) The presence of pyrocatechol and the naphthols is confirmed, although the quantities present could only be gauged approximately.

(*f*) The specific gravity of the low-temperature tar depends, in a considerable degree, on the content of rhetinols and mineral matter, and, in a minor degree, other constituents, and is not a safe guide as to the temperature of carbonisation.

In view of the substantial identity in constituents of the four tars, it was decided to continue the extraction work on much larger quantities of tars C and D only, in order to obtain such quantities of products as to allow of easy purification and more detailed examination. This work is detailed in Part III.

III.—EXAMINATION OF TARS C AND D BY MODIFIED SOLVENT EXTRACTION.

In order to obtain larger quantities of the various fractions in a state of greater purity, 5 kg. each of tars C and D were treated by extraction methods modified in the light of the results obtained in Part II. To ensure cleaner separation of the various constituents a preliminary steam distillation at a temperature of 140° was decided upon, as experiment indicated that decomposition did not occur at or below that temperature in the presence of steam. The steam-distilled portion and the residue were treated separately.

The steam distillation was stopped when the oil/water ratio in the distillate fell to 1/10.

Steam-distilled portion.—The steam distillation proceeded quietly, tar C giving off sulphur dioxide and hydrochloric acid in traces, tar D giving ammonia. The distillates were dark yellow oils, and the residues were black and almost solid, that of tar C being rather waxy and that of D somewhat sticky. The steam-distilled oils were separated, precisely as before, into neutral oils, phenols, bases,

and carboxylic acids, using the processes already given.

The following results were obtained expressed as weight percentages on the tars:

	Tar C.	Tar D
	%	%
Steam distillate composed of:—		
Neutral oils	15·1	10·7
Phenols	6·5	4·1
Bases	0·2	0·33
Acids	0·07	0·02
Total	21·87	15·15

The steam distillation did not give a clean cut, but "tailed off," and therefore can only be considered as an expedient to assist the examination. The neutral oils and phenols were completely soluble in light petroleum. The results of further examination of the products are given later.

Examination of residues.—Preliminary testing showed that alcohol removed a portion only of the residue obtained by steam distillation, and as the extracted material contained "ulmins" which it was desired to leave behind as a residue, alcohol extraction was abandoned. Ether was ideal for the purpose, but was impracticable on a technical scale, but benzol was found to be almost as effective as ether in removing non-ulmin substances and also in possessing to only a small degree, the property of dissolving "ulmins" in the dissolved oils and phenols. Benzene was, therefore, used as a solvent, and the extraction was carried on until the benene was only slightly coloured. A considerable amount of "ulmins" was obtained from each tar by this method. The benzene solutions were diluted with solvent until precipitation ceased.

Phenols.—The phenols were extracted from the benzol solution of the tars in the usual way, no difficulty being encountered; neutralisation was carried out with carbon dioxide and the mother liquor extracted for carboxylic acids. After washing the benzene solution of tar D with caustic soda, an asphaltic substance separated out. This was provisionally relegated to the "asphalt" group. Tar C apparently contained none. The phenols were precipitated as a viscous mass with a high specific gravity, and, after neutralising with hydrochloric acid, were dissolved in ether and recovered as usual.

Bases.—The benzene solutions of the oils and bases were, as before, unworkable with ordinary washing with 1:3 hydrochloric acid. It was found, however, that complete precipitation of this material could be attained by saturating a benzene or petrol solution with a current of dry hydrogen chloride, when rapid absorption took place, with rise of temperature and precipitation of large quantities of dark, sticky material. This precipitation was complete, and the product was insoluble in benzene, petrol, ether, and water, but was soluble in alcohol; it was converted into the free base by caustic alkali and could then be precipitated afresh with acid. Treatment with gaseous hydrogen chloride before removal of the phenols yielded a precipitate containing large quantities of phenols, thus following known work as to the relative order of extraction to be followed.

The benzene solutions were treated, as above, until precipitation was complete, and the precipitate and solution washed thoroughly with water. The water solution contained the ordinary bases and was made alkaline and treated as usual. The bases obtained were of the usual type. Traces of ether-insoluble bases were again noticed.

Bases (acid-water insoluble).—The acid precipitates from the above were washed thoroughly with benzol and, after removal of solvent, were dissolved in 94% alcohol. "Ulmins" were again obtained in quantity, and were filtered off and added to those already obtained. The alcohol was distilled off, the residue treated with excess of 10% caustic soda solution and warmed, the liberated bases dissolved in benzol, dried, and recovered.

Neutral oils.—The benzene solutions, after treatment with hydrochloric acid and subsequent washing, were treated as usual, and the residual oils dissolved in light petroleum. Tar C oils dissolved practically completely, but tar D threw down a further quantity of asphalt-like material differing from the first in being soluble in benzene. This was washed thoroughly and returned as "asphalt" (benzene-soluble). The petrol solutions were distilled and the residue returned as "neutral oils" (petrol-soluble).

Separation of phenols.—The mixed phenols obtained were treated with light petroleum, when the larger portion remained undissolved. Petrol was added to the solution until precipitation ceased and the dissolved phenols were recovered. Three extractions of the residual rhetinols were carried out, and, in the last, heat was applied with very little result, as far as extraction was concerned. The solvent was removed from the residues, which were re-dissolved in ether, when further small quantities of "ulmins" were separated. The ether was recovered and the residues were taken as rhetinols.

The petrol-soluble phenols were viscous liquids with strong phenolic odour. They were distilled under reduced pressure through a fractionating column until the "break" occurred, and the residue in the flask was again treated with light petroleum, when more rhetinols were isolated and added to the main bulk. The petrol-soluble phenols were recovered and added to the distillate.

Percentage by weight.	Tar C.		Tar D.	
Neutral oils				
Petrol-soluble				
Steam-volatile	15·1	14·5	10·7	34·8
Residual	29·4		24·1	
Petrol-insoluble

		100·0		100·0
				0·2

Comparative results.—The preceding table gives the results of this examination of tars C and D. Both tars contained the same products with the exception that tar C apparently contained no asphalts.

The simplification of the method of examination has reduced the number of products, but much further work is necessary before a technical process can be elaborated or before any investigation of the composition of the products can proceed.

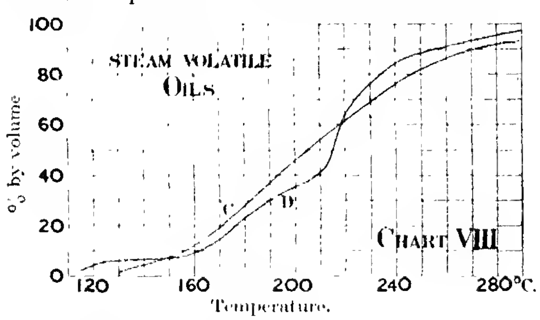
IV. PRELIMINARY EXAMINATION AND CHARACTERISTICS OF PRODUCTS OBTAINED IN SECTION III.

Neutral oils The steam-volatile oils from tars C and D gave distillation figures as follows when fractionated through a four-pear dephlegmator :—

Vol. % boiling below	Tar C	Tar D.	Vol. % boiling below	Tar C	Tar D.
100°		0·4	200°	18·0	37·2
120°	0·1	4·0	220°	65·2	70·8
140°	2·5	6·2	240°	80·0	88·0
160°	12·5	10·6	260°	89·7	93·0
180°	30·0	22·6	280°	93·5	96·6

The above figures confirm those previously obtained. The fraction of tar D oil boiling between 200° and 240° contained considerable quantities of naphthalene which crystallised out on cooling.

The detailed examination of the fractions shown graphically in Chart 8 was postponed for further work, but the presence of aromatic compounds, naphthenes, and paraffins in both tars was confirmed.



Residual oil.—While it is realised that the division of the neutral oils into "steam-volatile" and "residual" is purely arbitrary, it was found convenient to keep the rough divisions as such until further investigations can take place.

The residual oils from both tars were moderately viscous, clear, orange-brown oils, that from tar C being more orange than that from tar D. Both oils deposited crystals of paraffin on cooling. The oils had a remarkably high density, showing a high degree of unsaturation, viz., d^{15}_{15}, tar C, 1·048 ; D, 1·042.

A distillation conducted from a Wurtz flask gave the following figures :—

	Tar C.	Tar D.
Vol. % distilling below	%	%
300°	21	16
320°	33	26
340°	48	38
360°	61	52
Pitch	90	87
Sp. gr. of distillate	1·023	1·017

Decomposition took place during the distillation, particularly above 360°. The residues in each case were porous and apparently coked. The distillates were orange-brown in colour, with strong green fluorescence, were much less viscous than the undistilled oils, and were very similar to each other in appearance. Ordinary distillation is not indicated in the treatment of these oils, and the products obtained are apparently similar to those obtained by Fischer and Gluud and claimed by them to have value as lubricants. Both oils were completely soluble in benzene, acetone, light petroleum, chloroform, pyridine, and ether, but very slightly soluble in 94% alcohol. Concentrated sulphuric acid produced a violent reaction and no separation of unsulphonated oil took place. Methyl sulphate dissolved about 40–50% of the oils.

The inference can be drawn that these heavy oils consist mainly of very unsaturated compounds of complex structure. A thorough investigation is necessary before anything further can be said as to their possible uses or composition. The tars B and S are probably more paraffinoid than tars C and D, but undoubtedly the nature of the coal has a material bearing on this factor.

It is certain that no process will produce from these low-temperature tars, oils suitable for creosoting timber, or for the usual purposes for which coal-tar creosote is used. New uses must, therefore, be found for these products. Fischer and his co-workers have claimed that they possess lubricating properties, but little can be hoped for commercially in this direction, and new outlets must be obtained.

Asphaltic material. This term was used, in the absence of a better, for hydrocarbon materials which were insoluble in light petroleum, but which fall into none of the groups of products which have been isolated.

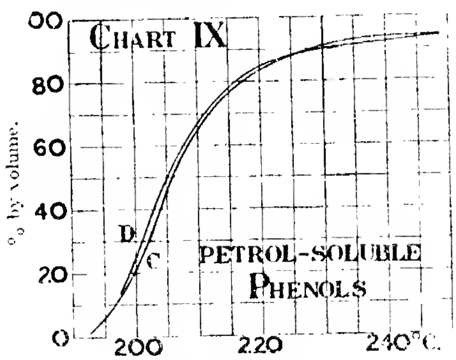
The two asphaltic residues found in tar D were found to be impure, containing "ulmins" and acid-water-insoluble bases, but, after re-treatment, a definite product was obtained, which was easily and completely soluble in benzene, insoluble in light petroleum, only slightly soluble in ether, and insoluble in 94% alcohol. The material was very viscous, sticky and black. Distillation commenced at about 320°, but the temperature rose very rapidly until barely 10% had distilled at 360°. Some 50% of distillate was obtained, but this material appeared to have a phenomenally high coking temperature as the flask became red-hot, with only a film of coked material, while the remainder boiled quite steadily. The distillate was extremely viscous, the later fractions setting to a solid rubbery consistency. Sulphur compounds were present in quantity but decomposition was apparently surprisingly small. No phenols were produced in the distillation nor were ammonia or basic compounds present.

Owing to the difficulty of treatment, little more can be done with this material. It is noteworthy, however, that definite asphaltic compounds have only been obtained from tar D, which shows definite signs of high-temperature products; all other materials provisionally termed asphalts found in Section II. were found to be mixtures and to contain

ttle or none of this product. It is probable that he production of this material is in some way linked p with the production of the aromatic compounds nd is a sign of high-temperature carbonisation.

It is certain that the presence of any large proporion of this material would give the pitch the peculiar roperties which renders high-temperature pitch f value. Little of this remarkably high-boiling nd stable series of compounds can ever be brought ver in ordinary tar distillation and any present must remain in the pitch.

Petrol-soluble phenols.—The steam-volatile phenols and the petrol-soluble phenols obtained from the esidual products were found to be composed almost ntirely of the homologues of phenol, and to contain no methoxyl compounds nor more than traces of ihydric or trihydric phenols. The phenols from ar C and tar D were substantially identical in boiling point, as shown in Chart 9. The actual constituents of this phenolic portion require further extensive



investigation, but little can be accomplished by the present known methods. There is evidence that this series of phenols constitutes the main bulk of the high-boiling blast-furnace tar acid of commerce, which is often stated to contain no homologues of phenol. The remainder consists of rhetinols, which appear to distil unchanged in the presence of phenol homologues.

Rhetinols.—This series of compounds is one of the most interesting products of this investigation. The product obtained after fairly thorough purification by alternate solution in ether, alcohol, alkali, and extraction with light petroleum, is a clear, dark, very sticky, resinous substance, d^{15} 1·115, bright orange-brown in colour in thin layers, with no definite melting point, softening at about 30° and melting to a thick sticky liquid below 100°; it is completely soluble in ether, alcohol, and most organic solvents, but completely insoluble in water and almost completely insoluble in light petroleum and carbon tetrachloride. The product retains "ulmins" most tenaciously, and the purified product so far obtained does not appear to be completely free from this impurity. The purified product is practically tasteless, and has only a faint tarry odour. It is insoluble in solutions of alkali carbonate and bicarbonate, easily soluble in weak caustic alkalis, giving a clear brown solution which foams on agitation. This characteristic is most noticeable. An alcoholic solution gives only a slight brown coloration with ferric chloride; chloroform and alkali gives no colour reaction, while the Liebermann test for phenols and the Liebermann-Storch reaction given by colophony and resin acids give negative results. Bacteriological tests appear to indicate a disinfectant value rather greater than that of tricresol.

The rhetinols can be sulphonated smoothly with ordinary concentrated sulphuric acid, a moderate temperature being developed on mixing, and the sulphonated product is soluble in water, the solution precipitating gelatin solution.

Addition of potassium ferricyanide to the alkali solutions of these rhetinols produces brown, amorphous precipitates, soluble in pyridine, and generally, as far as can be at present ascertained, identical with the "ulmins" obtained from the tars. On sulphonation these artificial "ulmins" do not produce completely water-soluble compounds, thus differing from those prepared by Marcusson, who thus distinguishes between artificial "ulmin" products produced from tars and natural products from coal. There would also appear to be some evidence that, on standing (and also possibly by the action of reagents), the rhetinols are gradually converted into "ulmins" Owing to the great difficulty of complete purification, judgment on this point must be suspended They absorb bromine rapidly, giving dark amorphous products.

When distilled at atmospheric pressure, the rhetinols commence boiling at about 300°, with decomposition into water, homologues of phenol, aromatic hydrocarbons, and pitchy residues, with at least 40% of the rhetinols passing over apparently unchanged. At 11 mm. pressure the decomposition still takes place. The product could therefore not be purified by distillation. The rhetinols appear to be the intermediate stage between "ulmin"-like compounds in the coal and the homologues of phenol, and the first stage of the process is one of reduction. Distillation of the "ulmins" from the tars, or of the artificial "ulmins" alone, does not appear to produce either rhetinols or phenols. A distillation at atmospheric pressure through a 4-pear fractionating column, keeping the top of the column at 300°, and re fractionation and separation of the distillate, gave 4% of water, 12—15% of homologues of phenol, 7% of neutral oils, and over 50% of a very brittle pitch. Even under these conditions some 25% of the rhetinols distilled unchanged. The distillate contained in abundance the substances producing the crimson colour with alkali, the alkaline solution becoming intensely crimson. The rhetinols were free from any trace of this material; there is, therefore, no escape from the conclusion that this colour-producing material is a product of decomposition of the rhetinols, and its absence from any distillate is due either to the absence of rhetinols or to the presence of sufficient homologues of phenol

to permit little or no decomposition of rhetinols during distillation.

Ammonia and hydrogen sulphide were given off during the distillation, and nitrogen was present in the rhetinols. This may be present as an impurity only, but ordinary bases were eliminated in the purification; none the less, purification is extremely difficult and judgment must be reserved.

The complete decomposition of the rhetinols is very difficult. A plain distillation commences at 290°—300°, and the temperature rises steadily, whilst the distillate may amount to two-thirds of the original material. This again decomposes on distillation, but decomposition is slow owing to the formation of mixtures of undecomposed rhetinols and the decomposition products.

The pitch produced is extremely brittle, insoluble in caustic alkalis, soluble in pyridine, but only yields traces to ether. The ether solution has, however, a brilliant yellow green fluorescence.

The homologues of phenol produced are typical products. Phenol is present in small quantity, but the main part appears to be composed of the homologues boiling between 210° and 240°.

A distillation of the phenols obtained from the foregoing experiment gave the following results:—b.p. 200°, volume boiling up to 210°, 7%; 215°, 20%; 220°, 47%; 225°, 60%; 230°, 75%; 240°, 83%; 245°, 94%. Phenol was detected in the aqueous portion of the distillate, and the results of distillation show that the homologues of phenol produced by destruction of rhetinols resemble those present in low-temperature creosotes. It is therefore probable that the latter have been formed in this way. The hydrocarbons produced were definitely aromatic in character and were of low boiling point, resembling the lower fractions of high-temperature creosote. The quantity obtained was insufficient for further investigation, and the foregoing results and findings may be subjected to modification in future work on larger quantities. As stated previously, purification is most difficult, and there is very strong reason to believe that the product is unstable on keeping, "ulmins" being apparently produced on standing. There would also appear to be a close affinity between the rhetinols and the acid-water-insoluble bases.

During the purification of the rhetinols a small quantity of light brown, amorphous, "ulmin"-like material was obtained which differed from that previously dealt with, in being completely soluble in aqueous caustic soda and cold alcohol. Sodium carbonate solution dissolved only traces on boiling. This material would appear to be similar to the products classed under the term "ulmic acid," but again, a close examination will be necessary before any definite statements on the point can be made.

The presence of rhetinols and of the residue from decomposed rhetinol, together with the large percentage of "ulmins," is probably the main cause of the brittleness of low-temperature pitch, and not a large proportion of paraffins as suggested by Marcusson. In the author's experience the presence of paraffins does not give the glass-like, brittle pitches given by the tars worked upon.

The importance of these rhetinols cannot be overestimated. There is no evidence that such products are present in the coal, but they are undoubtedly a half-way stage between some primary coal constituent and the homologues of phenol found in coal tar. The author desires to reserve the further investigation of these substances to himself and his colleagues.

"*Ulmins.*"—Under this description have been put all the brown amorphous substances insoluble in ether or petrol but soluble in pyridine, which have been obtained in quantity from the tars. The author has used the term "ulmin," inasmuch as the materials described in the literature as "ulmins" appear to coincide in general characteristics with the material obtained, but it is not intended to suggest that the "ulmin" is identical with that obtained from coal.

The "ulmins" obtained are brown, amorphous substances insoluble in water, petrol, or ether, but partially soluble in chloroform, boiling alcohol, and benzol; completely and easily soluble in pyridine, phenol and its homologues, and rhetinols. In their characteristics these materials closely resemble the material extracted from coal with pyridine and are undoubtedly Marcusson's "tar resins."

The "ulmins" are readily sulphonated, dissolving quietly in sulphuric acid to a dark red-brown solution. The sulphonated product does not dissolve completely in water, a light flocculent substance separating from an apparently colloidal solution, which foams on shaking. The "ulmins" themselves are insoluble in caustic alkalis, and boiling does not give even a colloidal suspension. Extraction with solvent showed that the products obtained were by no means homogeneous, hot alcohol extracting a portion, benzene a further quantity, and, generally, even on this section, much investigation is necessary before coming to any definite conclusions.

Acid-water-soluble bases.—These bases were of the usual type of high-boiling coal-tar bases, possessing the normal basic odour and dissolving in aqueous acids to orange-coloured solutions. The proportion of secondary bases was high, and primary bases seemed to be absent. No detailed examination has yet been possible.

Acid-water-insoluble bases.—These compounds are very remarkable, apparently forming salts insoluble in water. The purification of the material obtained in the examination was attempted by re-solution of the basic material in benzene and re-precipitation with dry hydrogen chloride. The precipitated material was dissolved in alcohol and the ever-present traces of "ulmins" removed, and the alcohol-soluble material dissolved in ether, after warming with alkali. From ether, dilute hydrochloric acid removed the bases as a very voluminous, gelatinous precipitate which emulsified the layers of ether and acid, so that dry hydrogen chloride again was used as precipitant. Very serious losses occurred in this attempt at purification and it would

appear that the product is extremely unstable. The purified product was a practically solid, resinous substance, d^{15} 1·14, soluble in ether, from which it was removed almost entirely by aqueous hydrochloric acid as a brown, flocculent precipitate which passed, on warming, to a black, resinous mass, practically insoluble in water. On distillation the purified free base began to boil at 280° and the temperature rose rapidly to over 400°, about 50% only distilling, the remainder being pitch. The distillate, which was orange in colour and viscous, appeared to consist almost entirely of acid-water-soluble bases of very complex character. Ammonia was not detected during the distillation, which would tend to show that the ammonia produced by distillation of the rhetinols was not due to admixture of this material. Better means of purification are being sought, when larger quantities of material become available for further examination. The existence of these bases affords, no doubt, an explanation of the low yield of ammonia and nitrogeneous bases of the usual type in low-temperature tar work. The material undoubtedly remains undecomposed in the pitch, and assists in rendering it brittle. No use can, at present, be seen for this material.

Carboxylic acids.—The purified products were brown resinous solids with a peculiar coconut-like odour. Slight signs of crystallisation were occasionally observed, but the crystals were soft and resinous, and could not be produced at will, or in a form suitable for purification. A minute quantity of flat, needle-shaped crystals was obtained by sublimation, but beyond negative tests for benzoic, salicylic, and allied acids, little could be done, as the total quantity was less than 0·1 g.

The acids appeared to have a strong resemblance to the resin acids, being soluble in ether and alcohol, but insoluble in light petroleum and carbon tetrachloride, even on boiling. The Liebermann-Storch reaction for abietic acid gave a negative result. The analytical constants obtained were as follows :—d^{15}_{15}, 1·22 ; mean mol wt. (calculated from neutralisation value to phenolphthalein), 227 ; iodine value (Wijs, 8 hours), 113. The specific gravity is extremely high and the iodine value agrees very closely with that calculated on the basis of the acids containing only one double bond. The product obtained differs entirely from that obtained by Marcusson, who considers his material to resemble humic acids. The material from these investigations resembles more closely the natural resin acids, particularly those semi-liquid acids present in rosin oil obtained by dry distillation of colophony.

V. General Summary.

1. The hypothesis that low-temperature tars closely resemble blast-furnace tar is shown to be substantially correct.

2. The tar produced by carbonisation of bituminous coal in continuous vertical retorts is also shown to be mainly the product of low-temperature carbonisation, and, although there may be present certain amounts of aromatic products, the general character of the tar is that of a low-temperature tar, and the products obtained by ordinary distillation have all the bad qualities of blast-furnace products.

3. Ordinary distillation of low-temperature tar produces products which are of low value, with the exception of high-boiling tar acid and fuel oil.

4. The method of plotting the gravity of successive fractions against the mean boiling point is valuable, in showing the presence of aromatic compounds, such as naphthalene, and also in the examination of the phenolic compounds.

5. The examination of tars by the solvent method, while full of pitfalls, shows a close similarity in composition of the four tars examined, and that the type of coal carbonised affects the respective proportions of ingredients, but the process of carbonisation is only important when carbonisation is carried out in a large volume of gas, when the lower-boiling products are washed out of the tar.

6. Low-temperature tar is shown to contain the following groups of products :—

(*a*) Ulmin-like substances, insoluble in ether, soluble in pyridine and phenols.

(*b*) Neutral oils, distilling up to and above 400°, containing paraffins, naphthenes, and aromatic compounds, but mainly consisting of highly unsaturated hydrocarbons.

(*c*) Homologues of phenol, with a new class of phenols (rhetinols) resinous in character and possibly containing nitrogen, distilling with decomposition at and above 300° but forming binary mixtures with phenol homologues in which the rhetinol distils unchanged.

(*d*) Basic materials of novel character, combining with acids to give salts insoluble in water.

(*e*) Much smaller quantities of carboxylic acids of a resinous character , pyridine and quinoline type bases ; traces of ether-insoluble bases, and of substances resembling ulmic acids.

7. The presence of tar resins and carboxylic acids claimed by Marcusson is confirmed, and the results of Tropsch are shown to be low, probably owing to the solubility of the ulmins in other constituents.

8. The absence of alcoholic compounds of the type found by Pictet and Bouvier is in agreement with the results of other workers.

9. The presence of pyrocatechol, α- and β-naphthol in the tars is in conformity with the results of Continental workers, but is of no technical value, as the quantity is too small.

10. The phenolic constituent of the creosotes produced from these tars is a mixture of homologues of phenol and undecomposed rhetinols. The statements that these phenols contain guaiacol and other methoxyl compounds, polyhydric phenols or diphenyl compounds, are definitely disproved. The

term "phenoloids" is unsound and should be abandoned.

11. The production of the colouring matter present in many of these creosotes is shown to be caused by destruction of the rhetinols during distillation, and the substance is probably either a condensed phenol compound present in a leuco form or a coumarone derivative.

12. The presence of asphaltic substances is definitely proved in tar D. It is doubtful whether such substances exist in true low-temperature tars.

13. The rhetinols are demonstrated to be an intermediate stage in the production of phenol and its homologues from some coal constituent, and it is suggested that the production of rhetinols is a reduction process from ulmin compounds, as oxidation of rhetinols produces ulmin substances.

14. The acid-water-insoluble bases are suggested as a similar intermediate stage to ammonia and pyridine bases.

15. The specific gravity of the raw tar is no guide to temperature of carbonisation, and Fischer's limits of 0·95–1·06 are incorrect.

16. The observations of Maclaurin are confirmed, but it is shown that his methods are incomplete, and give mixtures of products.

17. The production of orange-red viscous oils by Fischer and Glund is confirmed, but the value of the product is doubted.

18. The absence of any products of known technical value, particularly phenol, is abundantly proved, and it is clearly shown that the high value placed on low-temperature tar is not justified on present knowledge.

19. Owing to the difficulty of purification, no quantitative figures on single solvent treatment are of value, and no product can be taken as homogeneous without extensive purification. Much of the laborious chemical examination and ultimate analyses published are valueless for this reason, and the author has deliberately refrained from attempting such, until much more thorough purification can be accomplished.

20. The danger to the chemical and technical industry of what is termed "unintentional" low-temperature carbonisation is clearly demonstrated. No treatment of tars such as tar D will produce satisfactory materials for the purposes for which high-temperature tar products are at present used, and no technical use can yet be found for the main bulk of this type of tar.

The author intends to continue the investigation of the products obtained; he considers that an examination of high-temperature tar by the same methods will be of value, and proposes to include such an examination in future work.

As far as possible, every care has been taken to keep within the facts, and possibly the author has been over-cautious in interpreting and in drawing deductions. It is felt very strongly, however, that there have been far too many hypotheses and loose statements published in connexion with the subject, and, in view of the complexity of the problem as demonstrated so clearly in Section II., nothing but laborious and painstaking ground work will give a clear view of the problem to be solved, and, until the main facts are laid bare, the isolation of traces of easily found constituents, and the chemical investigation of unidentified mixtures, is confusing the issue and not adding anything to knowledge.

THE UTILISATION OF LOW-GRADE AND WASTE COALS IN POWER PRODUCTION.*

BY W. S. COATES.

A low-grade coal is one which is difficult to burn in a boiler furnace, and has a relatively low heating value. A waste coal is not necessarily low-grade. Its calorific value may be high, but owing to the large proportion of dust in it, it cannot command a high price. Some examples of these coals are given below:—

(1) *Duff* is the name given in Scottish, North of England, and certain Welsh collieries, to the poorest qualities of coal, generally in a fine state of division, obtained during dry screening. The name "smudge" is given to the same coal in Yorkshire and Midland collieries.

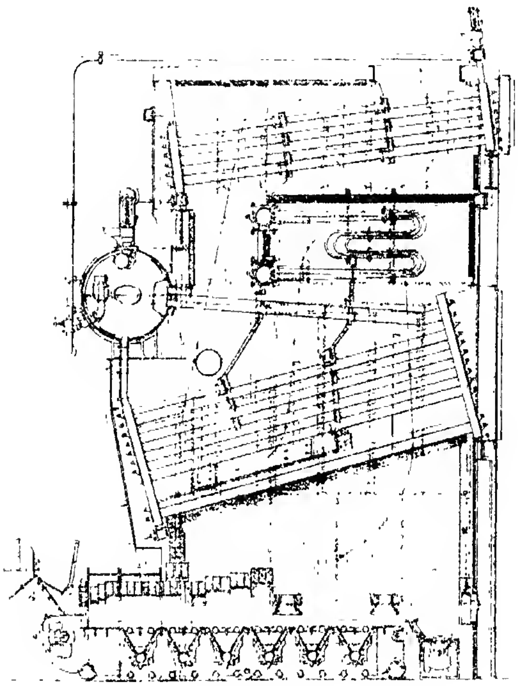

Fig. 1.

(2) *Splints* is a cannel coal which has a characteristic slatey structure, and decrepitates on heating. It yields a gas of high illuminating power by destructive distillation, and was formerly used in conjunction with gas coal for gas making. The coke does not "bind," but retains the original shape of the coal, and partly for this reason it is difficult to burn on a chain grate.

(3) *Bands*, the strata lying between the coal seam proper and the rock.

(4) *Pond duff* and *washer slurry*, the fine dust removed from the coal in the washing plant. The moisture content is exceptionally high and may reach 30%.

(5) *Rough smalls* is that coal, obtained during single screening, which passes through a $\frac{5}{8}$-inch screen. It generally contains therefore a relatively high proportion of fine slack and it is not unusual for 40–50% to pass through a $\frac{1}{4}$-inch sieve.

(6) *Dross*, is the name given to fine slack in Scotland.

(7) *Culm* or *gum* is the fine slack from anthracites.

A section through a Babcock and Wilcox water-tube boiler fitted with compartment type stoker and superheater, is shown in Fig. 1. The space occupied by the boiler tubes and economiser tubes (which are inclined at 15° and 8° respectively with the horizontal) is divided into three passes by horizontal and vertical baffles, the path of the hot gases through these passes is shown by the arrows. The steam generated in the boiler tubes rises together with the water, to the high end of the rear headers and is conveyed along the horizontal tubes to the front drum in which the steam is liberated. The water returns to the boiler tubes through the short tubes connecting the front headers to the drum. The steam is conveyed to the superheater (which is located at the top of the first and second boiler passes) by the dotted pipe, and it leaves the unit at the top superheater box.

The furnace.

Generally speaking it is much more difficult to consume completely the "volatile matter" evolved during the combustion of the coal, than it is to burn the carbonaceous matter in the coke.

The complete combustion of the hydrocarbon gases (methane, ethane, ethylene, benzene, etc.) presents no difficulties provided that there is an adequate supply of oxygen, that the temperature is above the ignition point (*i.e.*, at least about 1500° F. or 815° C.), and that combustion is completed before the cooler portions of the boiler are reached. The higher the proportion of the more complex hydrocarbon gases, the longer is the flame produced and therefore the more combustion space is required to prevent contact of the flame with the comparatively cool boiler surface.

The complex heavy hydrocarbons which are present in the tarry vapours are much more difficult to burn, partly because of the higher temperatures required for the reaction between them and oxygen, and partly because at the high temperatures existing in the furnace they may break down, free carbon

* Read at a meeting of the Newcastle Section on Nov. 28, 1923.

and much more complex substances being produced, which require still higher temperatures for complete combustion. If, therefore, the temperature of the reacting gases is lowered to a point below which the reaction cannot take place, black smoke results and passes through the boiler accompanied, in the majority of cases, by unburnt hydrocarbons and carbon monoxide. This chilling may be caused by flooding the combustion chamber with a large excess of cold air or by allowing the flames to impinge on the cool surface of the boiler tubes. When black smoke is formed it cannot be consumed in the boiler, no matter how much oxygen is present, because the existing temperature is much below the ignition point of the combustible matter in the smoke. The absence of black smoke does not necessarily indicate complete combustion, because carbon monoxide and other combustible gases may escape unaccompanied by carbon. The only satisfactory way to ensure complete and smokeless combustion is to maintain as high a temperature as possible in the furnace, an adequate supply of air for the reaction (though not in excessive quantities), and intimate mixture of the air with the combustible gases. The average speed of the gases through the combustion chamber may reach 20 to 30 feet per second at full rating, and up to 6 cb. ft. of volatile matter may be distilled off per pound of coal. Only a fraction of a second, therefore, is available in which the reaction takes place. If, however, an insufficiency of air is present for the tarry vapours, they may pass through the boiler unconsumed and a brown smoke will be emitted at the chimney. Brown smoke is, therefore, indicative of greater fuel losses than black smoke.

The foregoing remarks lead to the conclusion that the higher the proportion of volatile matter in a coal, the more difficult is smokeless combustion. In fact, it is found in practice that it is very difficult indeed to burn completely fuels containing more than say 27% of volatile matter. The famous Welsh steam coals contain between 10 and 15% of volatile matter and little ash; they are free-burning coals, that is to say the volatile matter distils off and is ignited at a comparatively low temperature, and are quite easily consumed without smoke formation. Generally speaking, so long as a coal is free-burning, the lower the volatile content the easier is smokeless combustion.

Induced draught is generally sufficient to consume completely a good grade of bituminous or semi-bituminous coals—that is, coals, free from slacks, of which the calorific value is above, say, 11,000 B.Th.U. per pound, the ash content is not high, and the volatile matter is such that ignition of the coal is easily obtained. Such coals generally swell and cake to some extent, and the resistance to the flow of air through the fuel bed which is thus set up brings about a thorough mixing of air and fuel. Under induced draught conditions, the fan has the double function to perform of drawing the air supply through the fire and of pulling the products of combustion through the boiler. It has been found, however, with certain classes of inferior coals having a calorific value below 11,000 B.Th.U. per pound, and a high ash and low volatile content, and especially if the proportion of slacks is high, that complete combustion is more easily obtained by assisting the air supply through the fuel bed. The "balanced draught stokers" have been designed with this end in view. In large power stations the bunker coal is of necessity a mixture of several classes of fair and low grade qualities, and it is often advantageous to be able to use either induced or balanced draught at will.

Fig. 1 shows a longitudinal section of the latest design of "compartment type" balanced draught stoker of Messrs. Babcock and Wilcox, Ltd. The quantity of coal burnt per hour is controlled by varying the speed of the grate by means of the eight-speed epicyclic gear-box interposed between the main drive and the grate drive, and also by varying the thickness of the fuel-bed by means of the guillotine door in front of the furnace. Closing-in doors are fitted to the stoker front, and by means of a forced draught fan, an undergrate air supply is fed into boxes mounted between the upper and lower portions of the grate. The air leaves the boxes through a number of narrow openings of variable width. The boxes are so proportioned that the air supply under each two feet length of the grate is under control. When these openings are wide open and the air pressure is suitably adjusted, a balanced draught is obtained at the fuel bed. The boiler can be operated as an induced draught installation, when the closing-in doors are open and the forced air supply is cut off.

A stoker which has been designed for burning fuels with a high volatile content, and such waste fuels as washer slurry which are high in moisture, is the Class E underfeed stoker manufactured by the Underfeed Stoker Co. This is shown in longitudinal and transverse sections in Figs. 2 and 3. C (Fig. 2)

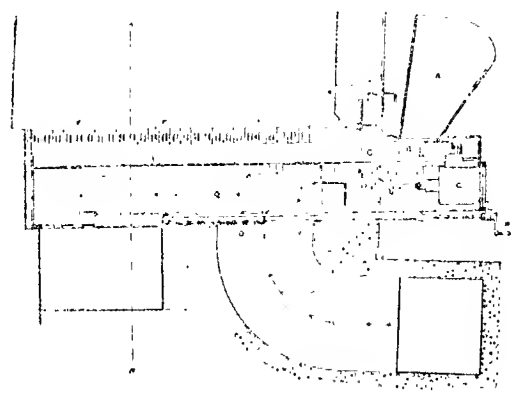

FIG. 2.

is a steam motor, the piston of which actuates simultaneously the sliding bottom, E, of the coking-retort, and the coal ram, B, which drives the coal into the retort from the bottom of the hopper, A. The coal is thus carried to the back end of the furnace and is forced to rise in the retort, ultimately overflowing on to the hollow grate bars, F, which are alternately fixed and moving. The moving bars work trans-

rsely to the retort, and receive their motion from e rocking bars, H, shown in Fig. 3. The clinker deposited on the dumping bars, K. The air supply ters the box, Q, below the coking-retort and part it passes through the openings, R, where it mixes th the volatile matter as it passes upward through

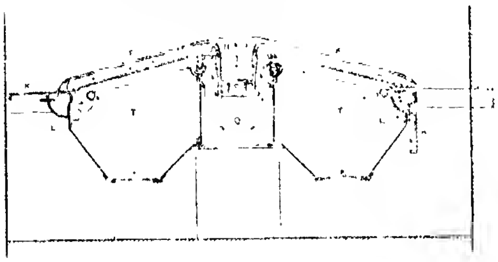

FIG. 3.

the incandescent fuel, the temperature of the reacting gases being therefore very high. The remaining air is heated on passing through the bars, F (which are thus kept cool), into the hot air chamber, T. From here the air rises and passes through the small spaces between the bars into the coked fuel.

Combustion of the carbon in the coke.

The reaction between carbon and oxygen has been studied by many chemists for over 100 years, but even to-day its mechanism is not clearly understood. At least two facts, however, appear to be established: (*a*) that whatever may be the conditions under which carbon and oxygen interact, both carbon monoxide and carbon dioxide are always produced; (*b*) that perfectly dry carbon dioxide is not reduced by perfectly dry carbon, even at bright red heat. It would appear, therefore, that no matter how excessive may be the air supply passing through the incandescent coke on the grate, carbon monoxide is always present in the gases above the coke, and therefore an adequate supply of oxygen above the grate, that is, in the combustion chamber is vital. The fact that perfectly dry carbon dioxide and carbon do not yield carbon monoxide, even at high temperatures, shows that water vapour plays a large part in the reactions taking place on the grate, but the rôle of the water vapour is, at present, unknown. Water vapour is always present in the air passing through the grate, and water is also present in the coal. Hence, if any carbon dioxide is produced in the lower layers of the incandescent coke it will be reduced to carbon monoxide as it passes through into the upper layers, the amount of carbon dioxide so reduced being dependent on the prevailing conditions. Above red heat carbon and carbon dioxide react under normal conditions, in accordance with the equation, $C + CO_2 = 2CO$, but, at the same time, some of the monoxide dissociates into carbon and carbon dioxide. Hence, a reversible system seems to be set up which may be expressed, $C + CO_2 \rightleftharpoons 2CO$. It will be noticed that an increase in volume occurs when the reaction proceeds from left to right; therefore a decrease in pressure at any given temperature would result in an increase in the equilibrium proportion of the monoxide, and *vice versâ*. The dissociation of carbon monoxide being an exothermic reaction, it is evident that an increase in temperature at any given pressure would favour the formation of the monoxide. This reversible system has been studied by Rhead and Wheeler, who found that the velocity of the reaction between carbon and carbon dioxide at any given temperature is many times faster than that at which carbon monoxide dissociates at the same temperature. The findings of Rhead and Wheeler may be summarised thus, the combined pressures of the gases being one atmosphere:—

	Relative percentages of	
Temperature, °C.	Carbon dioxide	Carbon monoxide
850	6.2	93.8
950	1.3	98.7
1050	0.4	99.6
1200	0.06	99.94

It is not implied, however, that whatever the temperature of the fuel bed may be, the above proportions of monoxide and dioxide corresponding to that temperature will be found in the gases as they leave the fuel bed. These results lead to the conclusion that the larger proportion of such gases is carbon monoxide, but there does not appear to have been much work done on the analysis of the gases immediately above the fuel on a chain grate.

The combustion of 1 lb. of carbon to the dioxide is accompanied by a heat evolution of about 14,600 B.Th.U., whereas only 4400 B.Th.U. accompanies the combustion to the monoxide. A direct loss thus results of over 10,000 B.Th.U. per lb. of carbon incompletely burnt. The importance of an adequate air supply above the fuel bed is, therefore, evident, and it is of equal importance to ensure thorough mixing of the air supply with the combustible gases. The best practical method of achieving this is the avoidance of thin places in the fuel bed and of bare wings and dumping bars, since the incoming air will take the lines of least resistance and in all probability pass straight through the combustion chamber and into the flues.

An efficient furnace is one in which as much as possible of the energy in the coal is converted into heat. The chief losses are:

(1) The heat carried away by the nitrogen present in the air required for combustion, which cannot of course be avoided. Although the difficulties seem to be insurmountable at present, a probable future development will be the enrichment with oxygen of the air supply to the furnace. The nitrogen : fuel ratio will thus be reduced, and much higher rates of combustion will be possible.

(2) The heat carried away by excess air over and above that required for combustion. It is impossible to burn any fuel with the theoretical air supply; at least 25% over and above this is required when burning coal on a grate. The actual excess required depends entirely on the characteristics of the coal and cannot be calculated. That air supply is adequate which will burn the coal with the production of the highest amount of carbon dioxide in the flue gases, unaccompanied by combustible gases.

If carbon could be burnt with the theoretical air supply, the gaseous products would contain 21% of carbon dioxide. The average semi-bituminous

Journal of the Society of Chemical Industry.

coals contain 3—4% of hydrogen, and the gaseous products obtained by burning these in the theoretical air supply would contain 18·5% of carbon dioxide. It should be possible to obtain 14% of carbon dioxide in the waste gases after complete combustion of a coal of fair quality, this representing about $(18{\cdot}5/14 - 1) \times 100\%$ of excess air, that is, slightly over 30%. With a low-grade coal like duff, it is almost impossible to obtain complete combustion with more than 10—11% of carbon dioxide. This represents 85% and 70% of excess air. By exercising careful control over the furnace, this excess air can be kept at a minimum, but it cannot be eliminated.

(3) The sensible heat in the ash and clinker cannot be recovered, and fortunately it is not high. Very heavy losses may, however, be incurred by the imprisonment in, or absorbtion by, the ash of carbonaceous matter. The fusion temperature of ash varies considerably, but is generally between about 2000° and 2800° F. (1095° and 1540° C.), being usually lower in a reducing than in an oxidising atmosphere. If the ash softens during its passage through the furnace, absorption of carbon by it is inevitable, thus effectively preventing combustion of that carbon. Pieces of coke may also be imprisoned in the clinker and consequently would be isolated from the air supply. If a coal contains 25% of ash and the ash contains 20% of combustible matter, a direct loss of $(20/100) \times 25\%$ or 5% of the coal is incurred: this loss is difficult to avoid when the ash has a low fusion point.

A high furnace temperature is essential for high efficiency. This is obtained by burning the fuel completely at as high a rate as possible, with as little excess air as possible. With fuels containing much volatile matter, higher rates than 25—30 lb. of coal per square foot of grate area per hour cannot, generally speaking, be maintained without the production of smoke.

Some fuels are met with which are not free-burning although they may contain over 15% of volatile matter. These can only be consumed completely under forced draught, whereby a more thorough mixing of the fuel and air supply is obtained.

The compartment type balanced draught stoker shown in Fig. 1 may be used for these fuels. If the openings of the forced air boxes are made narrow, the undergrate air supply leaving them, is divided into many streams travelling at a high velocity. The air pressure requires to be increased over that necessary for balanced draught conditions, but the narrow openings obviate too large an excess of air passing through the fuel bed. The effect is, in fact, similar to that on a blacksmith's forge.

It has been found advantageous to wet a coal containing much duff or slack. The actual effect of this wetting is not clearly known, but in spite of the loss entailed in evaporating the added water, the following facts indicate the benefits which are obtained: A higher percentage of carbon dioxide in the flue gases and consequently a higher furnace temperature; an increased fuel consumption per square foot of grate area; less combustible matter in the ash and clinker, which is more friable and easier to handle; a more uniform density of the fuel bed, with consequently a more even distribution of the air throughout it.

When burning low-grade coals the furnace temperature is never as high as when burning better coals, partly owing to the lower calorific value of the former and also to the greater excess air required for complete combustion.

The boiler.

The transmission of heat from the fire to the absorbing surface takes place in two ways: by direct radiation from the incandescent fuel on the grate and from the flame in the combustion chamber, and by convection and conduction through the water tubes from the hot gases traversing the boiler passes.

Radiation.—Probably the larger proportion of the heat absorbed by the boiler is radiated to it, the energy so received by the gas side of the water tubes being conducted by them, as sensible heat, to the water on the other side. Stefan found that the amount of heat radiated from an incandescent "black" body, that is one with a dull surface, is proportional to the fourth power of its absolute temperature. The value of this law from a furnace operating point of view is exemplified by the case of two furnaces, the temperature of one being 2500° F. (1370° C.) and of the other 2700° F. (1480° C.). The latter furnace theoretically radiates more heat than the former in the ratio of nearly 1·3:1, that is to say, that increasing the furnace temperature by 200° F. from 2500° F. results in about 30% more heat being radiated to the absorbing surface. Hence the supreme importance of maintaining as high a furnace temperature as is consistent with complete and smokeless combustion.

Convection and conduction.—If the opposite sides of a steel plate 1 in. thick and 1 sq. ft. area are maintained at a constant temperature difference of 1° F., 450 B.Th.U. will be conducted through the plate, at a uniform rate, per hour. If the temperature difference is $d°$ F. and the thickness of the plate is t in., the amount of heat passing through each square foot per hour will be $450d/t$ B.Th.U. If the temperature on the gas side of the water tubes in a boiler is 1600° F. (870° C.), and on the water side is 500° F. (260° C.), the amount of heat passing through a 3/8-in. thick steel plate will be $450 \times 1100 \times 8/3 = 1{,}320{,}000$ B.Th.U. per square foot per hour, which is equivalent to an evaporation of $1{,}320{,}000/970$, or nearly 1400 lb. of water per square foot of heating surface per hour. In actual practice, between 5 and 6 lb. of water are evaporated per square foot per hour. This enormous difference is explained by the presence of a non-conducting gaseous film on the gas side of the water tube and of a water film separating the water from the tube on the other side. It has been found that a better heat transmission is obtained by maintaining a high velocity of the hot gases and also by causing them to flow at right angles to the tubes rather than along them. The object of the horizontal and vertical baffles in a water-tube boiler is thus explained. The above calculation also shows that the material of which the tubes are made and the

thickness of the plate make little difference to the heat transmission.

Owing to the fact that the waste gases leave the boiler unit at a higher temperature than the air supply enters it, a certain proportion of the heat in the coal is lost, which is roughly $100t/T\%$, where $t°$ F. is the temperature of the gas and $T°$ F. the temperature of the furnace. The temperature of the gases leaving the boiler itself cannot be lower than the saturation temperature of the steam; thus, in the case of a boiler working at 250 lb. pressure, the temperature of the gases cannot be lower than 420° F. (216° C.). In practice the gas temperature is always much higher than the saturated steam temperature. Some of this heat is, however, recoverable either in water economisers which preheat the feed water entering the boiler, or in air heaters which preheat the air-supply for the combustion of the coal.

Any factors, therefore, which result in a poor heat transmission through the boiler heating surface and give rise to too high waste-gas temperatures (such as scale or dirt on the tubes or short-circuiting of the gases between passes owing to faulty baffles) will lower the efficiency of the unit.

Another source of loss which should not be overlooked is the dissipation of heat from the boiler walls and the steam piping. The latter can be cheaply and efficiently lagged with a preparation of magnesia and asbestos. An ideal boiler casing would be a thick brick wall lined with white glazed tiles on the outside; this would, of course, be much too costly in practice. Modern practice is to enclose the boiler in a double steel casing; the annular space contains stagnant air which is an effective heat insulator. Those boilers which are encased in brick walls should be thickly tarred on the outside to prevent the infiltration of air as far as possible.

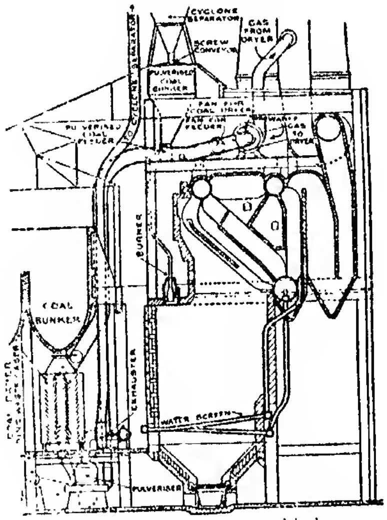
Pulverised fuel.

Pulverised fuel is not used extensively in this country for steam raising purposes, but during recent years rapid strides in this direction have been made in America and on the Continent, and successful results obtained. So far as our present experience enables us to judge, low-grade fuels can be efficiently utilised under boilers by pulverising, mixing with the necessary air, and burning the mixture under the same conditions as a gaseous fuel.

The very large surface area of the coal-dust ensures such an intimate mixture with the air supply that combustion is completed with a much smaller excess of air over that theoretically required, and a much lower content of combustible matter in the ash than is obtained with chain grate stokers.

It is only intended here to outline very briefly the two general systems which are adopted, illustrating one example of each.

In the "central system," which is generally adopted in large installations, the coal required for a number of boilers is prepared in a central pulverising plant. The powdered coal is stored in bunkers and conveyed to each boiler through a pipe line by a screw-conveyor or other suitable means, and is finally blown into the furnace as a cloud in the necessary air-supply for combustion, by means of a fan. Damp powdered coal has a tendency to cake rather than to flow easily, and for this reason it is usually necessary to reduce the moisture content of the original coal to 2 or 3% by drying in a current of hot air. Unfortunately, the drying plant adds considerably to the cost of the installation. The latest arrangement of the "Lopulco" system of the Underfeed Stoker Co., Ltd., is shown in Fig. 4. This installation is at



"Lopulco" system of pulverised fuel.

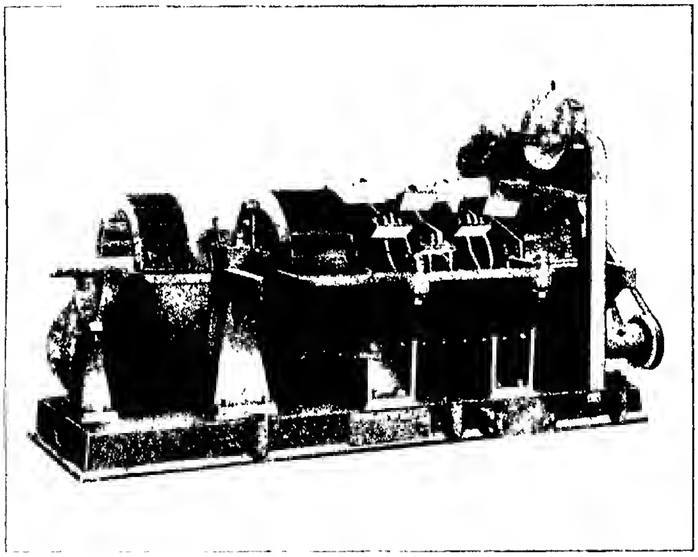
FIG. 4.

present being erected for the Société Anonyme Union d'Electricité, at their Vitry Power Station, Paris. There will be four Delaunay-Belleville boilers, each evaporating 140,000 lb. of water with a coal consumption of nearly 6 tons per hour, at normal load.

The coal is dried, in a portion of the flue-gases, on its way to the pulveriser, where it is lifted by means of a plough and thrown between the rollers of Raymond mills. The pulverised coal is carried away in an upward current of air, supplied by the exhauster, to the cyclone separator. The coal settles in the storage bunker, the air returning to the pulveriser. There is, therefore, a closed circuit including pulveriser, exhauster, and cyclone separator, thus eliminating the danger of explosion in the boiler-house through the presence of fine coal dust in the air.

There are ten burners to each combustion chamber, the capacity of which is 12,000 cb. ft. above the water-screen. The primary air for combustion is already mixed with the coal when it enters the combustion chamber. The secondary air, which is preheated by passing through the hollow furnace walls, is admitted through ports in the front wall of the furnace.

In the "unit system" there is a pulveriser for each boiler furnace. No bunkers or pipe-line for the powdered fuel are required, and, generally, it is not necessary to reduce the moisture content of the coal below 10%. A typical plant is the "Turbo" pulveriser manufactured by the Powdered Fuel Plant Co., which is shown, with the top cover removed, in Fig. 5. It consists essentially of a steel-lined cylinder containing a high-speed shaft co-axial with it, on which are mounted (1) a fan which draws air through the cylinder, and (2) steel beaters so arranged as to divide the pulverising compartment into four sections. There is ample clearance between the beater tips and the steel lining. The coal falls on to a distributor which feeds it into the first section of the pulverising compartment, where it is violently agitated. The smaller coal is drawn through each section until fine enough to be discharged by the fan into the furnace. The larger coal lags behind, owing to the high centrifugal force, until it is small enough to be carried away. The fineness of the coal is therefore determined by the speed at which the air passes through the cylinder, which is under control. The second fan shown in the illustration is external to the pulveriser, and supplies the secondary air for combustion, which may be cold or preheated.



The Turbo-Pulveriser.
FIG. 5.

The presence of "tramp" iron in the coal is a source of danger to the pulverisers. If it is present in large quantities a magnetic separator is necessary, but adventitious pieces of iron are usually eliminated by some device peculiar to each plant.

The disposal of the ash produced when burning powdered fuel under boilers has proved to be a difficult problem. Neglecting the grit which is carried through the boiler, the ash may be discharged in either the liquid or solid state. Provided that the combustion chamber is not too large, the ash can be maintained above its fusing temperature and discharged in the liquid state. There is, however, a tendency for the liquid ash to flux with the brickwork if its temperature is too high, and, on the other hand, if the temperature drops the ash may yield a pasty mass which might choke the outlet, thus necessitating a complete shut down of the plant.

The combustion chamber may be built large enough to ensure the temperature of the lower portion being below the fusion point of the ash, which may thus be discharged in the form of dust or nodules. The combustion chamber shown in Fig. 4 is fitted with a water-screen which consists of a number of tubes connected to the boiler. This screen is an effective portion of the boiler heating-surface being subject to the radiant heat of the furnace, and the temperature in the ash chamber below it is always lower than the fusion point of the ash no matter what the operating conditions may be.

Some of the more evident advantages of pulverised fuel firing over combustion in a mechanical stoker are briefly thus:

(1) Higher boiler efficiencies are possible owing to the lower excess air required for complete combustion and to the lower proportion of the combustible matter left in the ash.

(2) During no-load periods the fuel can be cut off, thus eliminating banked fires and stand-by losses.

(3) Practically all grades of fuel can be easily burnt.

(4) The control over the furnace is much more exible, and the fires can be instantly adjusted r any desired boiler rating.

The thanks of the author are due to Messrs. abcock and Wilcox, Ltd., the Underfeed Stoker Co., td., and the Powdered Fuel Plant Co., Ltd., for eir generosity in lending the blocks used for lustrating this paper, and in supplying information.

Discussion.

Dr. G. Weyman said that the efficiency of the generation of electricity from coal was in any case very poor in comparison with other methods of power production and therefore too much attention could hardly be given to the subject. As Mr. Coates had pointed out, there were still available large quantities of low grade and waste coal which could be used for the purpose. It seemed that for several reasons the coal should be either carbonised or completely gasified and the products burnt afterwards in the boiler plant. The volatile matter in coal needed so large an excess of air and required so large a combustion area that high efficiencies were almost impossible. The smoke and burning gases obscured a considerable proportion of the direct radiation from the red-hot solid fuel, and it was very doubtful if the boiler actually received the amount of heat by radiation from the fire that was usually reckoned on. The boiler plants of to-day appeared to have been entirely designed in relation to the combustion of the volatile portion of the fuel and depended upon the flame heat and convected heat of the excess of air passing from the furnace, and it was, in fact, customary to direct radiant heat back on to the fire in order to obtain accelerated combustion of the volatile matter. If the volatile matter were removed and the solid fuel then burnt under the boiler, the boiler and furnace could be designed to take full advantage of the radiant heat and would certainly be smokeless and more efficient.

Prof. Briscoe pointed out that in the combustion chamber the flame itself radiated much heat. Whatever the theoretical explanation might be, the experiments of Nicholson showed that in an ordinary Lancashire boiler the greater proportion of the total evaporation occurred in the immediate neighbourhood of the furnace. Present practice in boiler furnaces represented a mere opportunist development of the ordinary kitchen range and employed a principle which was essentially unsound. The fuel bed in any ordinary furnace was both a gas-producer and a means, frequently the sole means, whereby secondary air was admitted to burn the gas produced. It was inefficient, irregular in action, and uncontrollable in both functions. Conditions which promoted formation of combustible gas hindered the supply of air to burn it, and *vice versâ*; so that it was difficult to attain and quite impossible to maintain, even approximately, a correct adjustment of air to combustible matter. Clearly it would be much sounder to make the fuel bed efficient as a gas-producer and relieve it entirely of the function of supplying air. It would then be possible, by means of properly designed ducts and adjustable ports distributing a single forced or induced air supply, to maintain a proper ratio between the primary air supply (which would be wholly used in the production of combustible gas and might receive a proper addition of steam to control fuel-bed temperatures) and the secondary air supply, which could be maintained, within a few per cent., at the rate required for complete combustion.

TRAVANCORE ESSENTIAL OILS.—II. *OIL* FROM THE LEAVES OF *CALAMINTHA UMBROSA*, BENTH.

BY K. L. MOUDGILL, B.A. (CANTAB), B.SC. (GLASGOW), A.I.C.

Preliminary note.

The herb from the leaves of which this oil was obtained grows wild in some localities, notably Veapuram, Ayur, in Travancore, and is locally known as Karimthumba (Malayalam *Kari*, black). The leaves and the root possess a strong, pleasant and camphoraceous aroma, due to the presence of an essential oil which does not appear to have been examined before.

A large quantity of the leaves was collected for the author in September, 1923, by Mr. I. C. Chacko, Director of Industries, and distilled with steam in an air-dry condition (moisture = 40%) in a large copper still, when a 0·35% yield, calculated on the dry leaves, of a light yellow oil possessing a strong, rather complex, but not unpleasant odour, was obtained.

The oil had the following characters: d^{27}_{4}, 0·8854; n_D^{27} 1·4760; $[\alpha]_D^{30} = -45{\cdot}2°$, acid value, 0·5; ester value, 15·9; ester value after acetylation, 40·7; aldehydes by the neutral sulphite method, 6·5%. The oil was insoluble in 80% alcohol, sparingly soluble in 85% alcohol (7·8 vols.), soluble in 90% alcohol (0·7 vol.).

In view of the low density and refractive index of the oil, the difficulty with which it dissolves, even in 85% alcohol, and the ester values, it would appear to consist mainly of hydrocarbons. Only 70 c.c. of the oil were available for the following investigation.

Fractional distillation.

The oil dried over anhydrous sodium sulphate was distilled under reduced pressure, first over a boiling water bath (fractions 1–3) and then rapidly over a free flame, and the following fractions were obtained.

TABLE 1.

No.	B.p.	Pressure mm.	Yield %	n_D^{27}	$[\alpha]_D^{30}$
1	to 80	26	20	1·4687	62·5
2	80–85	26	32	1·4685	−68·3°
3	Above 85	26	14	1·469[illegible]	−73·8°
4	105°–110	17	27	1·4900	5·2°
	Residue and loss (by diff.)	..	7	—	

Fractions 1, 2, and 3 would appear to contain the same compound. Fractions 1 and 2 were mixed and distilled repeatedly over sodium under atmospheric

pressure, and finally 12 c.c. of a colourless oil were obtained, of b.p. 176°–177°; d^{27}_4, 0·8565; n_D^{27} = 1·4700; α_D^{30} = —73·35°. *l*-Limonene has b.p. 175°–176°; d, 0·8472; n_D^{27} = 1·4746; α_D^{30} = –105°.

Bromination of the oil yielded a halogen derivative which proved to be *l*-limonene tetrabromide.

In spite of repeated fractionation and distillation over sodium, the *l*-limonene separated from this oil was heavier but had a higher refractive index than pure *l*-limonene, probably due to the presence of small quantities of another hydrocarbon, which, however, could not be separated.

Fraction 4.—The aldehyde content of this fraction was found by the sodium bisulphite method to be 10%. The residual oil had n_D^{28} = 1·4930; α_D^{30} = + 5·4°; d^{28}_4, 0·9293. It was soluble in 3·4 volumes of 75% alcohol. At this stage, unfortunately, the small quantity of oil remaining was lost. In view of the ready solubility in alcohol it would appear to be an oxygenated product.

Summary

1. The essential oil from *Calamintha umbrosa*, Benth., is rich in hydrocarbons.

2. It contains *l*-limonene (about 65%), an aldehyde (6·5%), an ester, and an alcohol (12% if $C_{10}H_{18}O$).

3. Owing to its high hydrocarbon content, the oil is not expected to be of much direct use in perfumery.

THE ACIDS OF CAMEL HUMP FAT.

BY NORMAN McCLELLAND.

The hump of a young but full-grown and healthy camel (*Camelus dromedarius*) which died recently in the Wellington (N.Z.) Zoological Gardens, contained 80 lb. of fat with only a small amount of connective tissue. The investigation of the acids of this fat, which was steam-rendered, forms the subject of this note.

The only figures found in connexion with camel fat are the following by Henriques and Hansen[1]:—

[1] Abderhalden's "Biochemisches Handlexicon," III., 186; see also J.C.S. 1901, A, ii., 405.

Fat.	Iodine value.	Setting point.
Hide	38·7	34·5°
Stomach (oment)	36·5	35·0°

The values obtained by the author for camel hump fat are:—d^{100}_{15} 0·872; m.p., 35°—36°; insoluble fatty acids, 92%; unsaponifiable matter, 0·4%; saponification value, 205—206; iodine value, 37·4; m.p. of fatty acids, 45°—46°; titre value of solid fatty acids, 210—211.

The fat was saponified and the solid and liquid acids were separated by crystallisation from alcohol.

Solid acids.—The mixture of solid fatty acids after esterification with ethyl alcohol yeilded two main fractions on repeated fractionation at 15 mm.: (1) b.p. 195°—200° and (2) b.p. 210°—215°; there was also a small residuo boiling above 215°. Fraction (1) was identified as ethyl palmitate by its m.p., the m.p. of the methyl ester, and the m.p. and mol. wt. of the free acid.

Fraction (2) on similar grounds was proved to be ethyl stearate.

No pure substance could be isolated from the intermediate fractions, which appeared to be only mixtures of palmitic and stearic esters.

The residue boiling above 215° was found to consist of impure stearic acid. It is concluded that no higher fatty acids are present except possibly in very small quantity.

Liquid acids.—Lewkowitsch's modification of Hehner and Mitchell's bromide test having shown that acids giving tetra- and hexa-bromides were absent, the liquid acids were converted through the potassium and lead salts into the acid, and this into the barium salt, which was recrystallised and the acid then liberated. The oily acid had m.p. 11°, mol. wt. 280. From these results, the lead content of its basic lead salt, and the fact that it was converted by nitrous acid into elaidic acid and by alkaline permanganate into 9.10-dihydroxystearic acid, azelaic acid, and pelargonic acid, it was proved to be oleic acid.

The acids present in the fat are thus palmitic, stearic, and oleic acids; the approximate composition of the mixed fatty acids is palmitic 37%, stearic 16%, oleic 47%.

The author wishes to thank Professor Easterfield for a quantity of material.

ARYLAMINE SALTS OF THE NAPHTHALENESULPHONIC ACIDS. 1.—THE SALTS OF 2.6- AND 2.7-NAPHTHALENEDISULPHONIC ACIDS.

BY R. B. FORSTER, D.SC., PH.D., F.I.C., AND C. M. KEYWORTH, M.SC., A.I.C.

The arylamine salts of naphthalenesulphonic acids have been mentioned by various authors, but hitherto no systematic study of any one sulphonic acid has been published (*cf.* Erdmann and Suvern, Annalen, 1893, **275**, 297; Perkin and Cope, Chem. Soc. Trans., 1894, **65**, 845; Ambler, J. Ind. Eng. Chem., 1920, **12**, 1081; Lynch, *ibid.*, 1922, **14**, 964, Wales, *ibid.* 1922, **14**, 317; Perkin and Sewell, J., 1923, 27 T).

The 2.6 and 2.7 acids can be readily purified and identified by means of their arylamine salts and in a much easier manner than by means of their inorganic salts. The salts with amines differ widely in solubility. Thus the 2.6 acid can be readily separated from the 2.7 by means of the aniline salt. Certain amines, which are associated technically and which are not easily separated by ordinary methods, can be separated by means of their salts with 2.6- and 2.7-disulphonic acids.

The salts of the 2.6 acid are usually sparingly soluble in cold water and have a very high m.p. or are infusible below 360°, whilst those of the 2.7 acid are much more soluble and melt at lower temperatures, and are often difficult to crystallise from an aqueous solution. The arylamine salts of these acids may be obtained by several methods:—

(1) Addition of a cold concentrated solution of the hydrochloride of the base to a cold concentrated solution of the sodium salt of the acid and allowing to stand.

(2) Addition of boiling concentrated solution of the hydrochloride of base to a boiling concentrated solution of sodium salt of the acid, concentrating, and extracting the precipitate with alcohol if necessary.

(3) Addition of the sulphate of the base to the calcium salt of the acid.

(4) Addition of the free acid to the free base with the addition of a little hydrochloric acid.

Molecular quantities of acid and amine were taken, but a slight excess of amine and hydrochloric acid was always added. In general the salt crystallises on cooling and standing, but in a number of cases the mixture had to be concentrated and in some cases evaporated to dryness, and the residue extracted with alcohol. A large excess of the amine tends to inhibit crystallisation.

The salts, obtained usually, consist of 1 mol. of the disulphonic acid with 2 mols. of a monoamine, or 1 mol. in the case of a diamine. Acid salts, however, can be obtained of 1 mol. of base and 1 mol. of disulphonic acid, depending upon the relative quantities of each used.

All the salts are more or less soluble in water and also in ethyl alcohol, though in the latter solvent the solubility is usually much less. No other organic solvent (except, in a few cases, methyl or amyl alcohol) was found satisfactory for recrystallisation purposes. The salts can be precipitated from an alcoholic solution by the addition of ether, acetone, ethyl acetate, benzene, etc. The majority of the salts form supersaturated solutions which only crystallise on long standing or prolonged stirring. In most cases the salt is hydrolysed on boiling in aqueous solution; hydrolysis also occurs in alcoholic solution, though this can be prevented by the addition of a small quantity of hydrochloric acid or the hydrochloride of the base. In the case of the more sparingly soluble salts, the hydrolysis is not so very marked.

The purity of the salts has been checked by three methods. (1) m.p., (2) titration, (3) solubility. The titration was carried out as described by Perkin and Sewell (*loc. cit.*), a quantity of the salt suspended in water being heated to the boil and then titrated with $N/10$ sodium hydroxide, using phenolphthalein as indicator. The end-point is sharp. The solubility was determined by evaporating to dryness a weighed volume of the saturated solution of the salt.

Preparation of the pure 2.6 and 2.7 acids. A mixture of 2.6-, 2.7-, and 1.6-disulphonic acids prepared by sulphonating naphthalene in the usual manner, was separated, by the usual method, into the crude 2.6 disodium salt and the 2.7 disodium salt; the latter contains a considerable percentage of 1.6 salt. They were then purified by means of the aniline salts. It is necessary to allow sufficient time for the aniline 2.7 salt to crystallise out, as highly supersaturated solutions are formed which are very difficult to crystallise, especially when the 1.6 acid is also present. The aniline 1.6 salt is more soluble than the aniline 2.7 salt. The yield obtained is about 60% of 2.6 acid and about 30% of 2.7 acid, the remainder being chiefly the 1.6 acid.

All the halogen-substituted aniline salts of 2.7-naphthalenedisulphonic acid assume a reddish colour on exposure to moist air, and especially if very slightly impure. The 2.7- and 2.6-naphthalenedisulphonates of dimethylaniline, diethylaniline, and quinoline were difficult to isolate, as were also the monomethyl- and monoethyl-aniline salts of the 2.7 acid. In all cases the arylamine salt of the 2.7 acid was more soluble and of lower m.p. than the corresponding salt of the 2.6 acid.

In the laboratory the β-naphthylamine salts are convenient for obtaining the acids in a pure state, as β-naphthylamine 2.6-naphthalenedisulphonate is

only sparingly soluble in hot water, whereas the corresponding salt of the 2.7 acid is much more readily soluble (about 2 parts per 100) under the same conditions.

The β-naphthylamine 1.6-disulphonate was found to be more soluble than the 2.7 salt, and if present in not too large a quantity, will remain in solution while the 2.7 salt crystallises out.

In the case of the ring-substituted amines of the benzene series, the salts of ortho compounds are more soluble than those of the meta, and those of the meta more soluble than those of the para. The increase in melting point seems to follow in the order, *m, o, p.* The solubility in alcohol is usually in this order also.

Two salts of 2.6-naphthalenedisulphonic acid with *p*-toluidine were obtained, an acid salt consisting of 1 mol. of the base and 1 mol. of acid, also a normal salt (2 mols. of base and 1 mol. of acid), the former being much more soluble. In all other cases only the normal salts of monoamines were prepared.

The salts of diamines consisted invariably of 1 mol. base to 1 mol. acid.

All melting points recorded are corrected.

Experimental.

Aniline 2.7-naphthalenedisulphonate.—A hot solution of 19 c.c. of aniline and 23 c.c. of concentrated hydrochloric acid in 100 c.c. of water was added to a hot solution of 35 g. of crude sodium 2.7-naphthalenedisulphonate in 100 c.c. of water. On cooling and filtering a slight precipitate of aniline naphthalene-2.6-disulphonate separated, and on allowing the mother liquor to stand for two days, 15 g. of a mixture of aniline 2.6- and 2.7-naphthalenedisulphonates were obtained; on further standing 17 g. of practically pure aniline 2.7-disulphonate separated.

It is moderately soluble in ethyl alcohol and amyl alcohol and sparingly soluble in methyl alcohol and xylene, and practically insoluble in other organic solvents. On recrystallisation from alcohol it undergoes slight decomposition. It is best recrystallised from water containing a trace of hydrochloric acid, from which it is obtained in the form of white needles melting at 251–252°. It tends to form supersaturated solutions, especially if any impurities are present. Its solubility in water at 13° is 3·90 parts per 100 by weight. On exposure to moist air the crystals become reddish-pink.

Aniline 2.6-naphthalenedisulphonate.—A boiling solution of 4 g. of aniline and a slight excess of hydrochloric acid in 20 c.c. of water was added to a boiling solution of 5 g. of sodium 2.6-naphthalenedisulphonate in 30 c.c. of water. On cooling, the aniline salt separated out in the form of long needles or prisms. It is easily soluble in hot water but sparingly soluble in cold, 100 parts of water only dissolving 0·82 part at 13°. It is only slightly soluble in alcohol. When heated to 345° it darkens slightly but does not melt. 0·3694 g. required 15·15 c.c. $N/10$ NaOH = 99·5% theory.

o-Toluidine 2.7-naphthalenedisulphonate.—Owing to its solubility, this salt is very difficult to prepare. It was obtained by dissolving 10 g. of sodium 2.7-naphthalenedisulphonate, 7 g. of *o*-toluidine, and excess of hydrochloric acid in 30 c.c. of water and allowing the solution to stand a considerable time. It is very soluble in alcohol but insoluble in the usual organic solvents. It is best recrystallised from acidified water, from which it was obtained in white needles, m.p. 238°. On exposure to air it develops a green colour. Solubility in water at 15°, 6·1 parts per 100 by weight. 0·4592 g. required 18·0 c.c. $N/10$ NaOH = 98·5% theory.

o-Toluidine 2.6-naphthalenedisulphonate.—By dissolving 3·3 g. of sodium 2.6-naphthalenedisulphonate, 2·2 g. of *o*-toluidine, and 3 c.c. of glacial acetic acid in about 20 c.c. of water and allowing to stand overnight, this salt was obtained in the form of fine white needles, m.p. (decomp.) 338°. Solubility in water at 15°, 0·78 pt. per 100. 0·2116 g. required 8·5 c.c. $N/10$ NaOH = 100·5% theory.

m-Toluidine 2.7-naphthalenedisulphonate, obtained on cooling a solution of 5 g. of sodium 2.7-naphthalenedisulphonate, 3·3 g. of *m*-toluidine, and 3 c.c. of hydrochloric acid in 15 c.c. of water, crystallises from alcohol in fine needles, m.p. 211°. It is almost insoluble in the other usual organic solvents. Solubility in water at 20°, 3·37 pts. per 100.

m-Toluidine 2.6-naphthalenedisulphonate separated immediately on adding a solution of 3 g. of *m*-toluidine and 3 c.c. of hydrochloric acid in 10 c.c. of water to a solution of 5 g. of sodium 2.6-naphthalenedisulphonate. The salt crystallises from water in feathery needles, m.p. 329°. Solubility in water at 20°, 0·372 pt. per 100. 0·450 g. required 17·9 c.c. $N/10$ NaOH = 99·8% theory.

p-Toluidine 2.7-naphthalenedisulphonate was obtained by dissolving 5 g. of sodium 2.7-naphthalenedisulphonate, 3·3 g. of *p*-toluidine, and 3 c.c. of glacial acetic acid in the minimum quantity of water; on cooling, a good yield of the salt was obtained. It recrystallises well from 90% alcohol or water. From the former it was obtained in white needles m.p. 299°, which develop a yellow colour on exposure to air. Water at 15° dissolves 1·07 pts. per 100. 0·2572 g. required 10·15 c.c. $N/10$ NaOH = 99·1% theory.

p-Toluidine 2.6-naphthalenedisulphonate.—Both the acid and the normal salt were obtained in this case. 10 g. of *p*-toluidine dissolved in dilute acetic acid were added to a solution of 33 g. of sodium 2.6-naphthalenedisulphonate; the total volume of the solution was 210 c.c. On long standing it deposited white needles of the acid salt. These were recrystallised from acidified water but did not melt below 360°. Solubility in water at 20° = 1·51 pts. per 100. 0·2234 g. required 11·2 c.c. $N/10$ NaOH = 99·1% theory. On addition of a second molecule of *p*-toluidine to the solution, the normal salt was precipitated immediately. Like the acid salt, it crystallised in fine needles which do not melt below 360°. Solubility in water at 20° = 0·20 pt. per 100. 0·3576 g. required 14·3 c.c. $N/10$ NaOH = 100·3% theory.

a-Naphthylamine 2.7-naphthalenedisulphonate.—A solution of 3 g. of *a*-naphthylamine in 40 c.c. of water and 5 c.c. of hydrochloric acid was added hot to a solution of 4 g. of sodium 2.7-naphthalenedisulphonate. On standing overnight a good yield of crystals was obtained, which on recrystallising

from water had m.p. 305°—309°. Solubility in water at 20°, 0·85 pt. per 100. The crystals become violet on exposure to air. At 100° water dissolves its own weight of the salt.

a-Naphthylamine 2.6-naphthalenedisulphonate was obtained in a similar manner to the *a*-naphthylamine salt of the 2.7 acid, in fine feathery crystals which did not melt below 360°. Water dissolves 0·5 pt. per 100 at 15°. 0·4396 g. required 15·4 c.c. $N/10$ NaOH=100·6% theory.

β-Naphthylamine 2.7-naphthalenesulphonate.—A boiling solution of 4 g. of *β*-naphthylamine in 50 c.c. of water and 3 c.c. of hydrochloric acid was added to a boiling solution of 5 g. of sodium 2.7-naphthalenedisulphonate in 50 c.c. of water. The salt separated immediately in fine needles, easily recrystallised from water, m.p. 295°. Water dissolves 0·15 pt. per 100 at 15°. The solubility of this salt is much greater at all temperatures than that of the corresponding 2.6-disulphonate, and it may be used as a means of separating the two acids, especially if the percentage of the 2.6 acid is not very large. The salt of the 2.7 acid becomes yellow on exposure to air.

β-Naphthylamine 2.6-naphthalenedisulphonate, prepared in a similar manner to the salt of the 2.7 acid, is very sparingly soluble in cold water, 100 pts of water at 15 only dissolving 0·02 pt. of salt. It may be obtained in fine white needles by recrystallising from water. It does not melt below 360°. 0·1676 g. required 16·2 c.c. $N/10$ NaOH = 99·5% theory.

Separation of 2.6- and 2.7-naphthalenedisulphonic acids.—Separation by means of the *β*-naphthylamine salts. 5 g. of potassium 2.7-naphthalenedisulphonate, $C_{10}H_6(SO_3K)_2, 2H_2O$, and 3·5 g. of sodium 2.6-naphthalenedisulphonate, $C_{10}H_6(SO_3Na)_2.H_2O$, were dissolved in about 80°—100 c.c. of water, and the solution heated to boiling. To this was added a solution of 2·86 g. of *β*-naphthylamine in a like amount of boiling water and 4 c.c. of hydrochloric acid; the volume of the mixed solutions was approximately 200 c.c. On standing for 24 hours the *β*-naphthylamine salt of the 2.6 acid was filtered off; yield 6·30 g (99·0% of theory). To the filtrate more *β*-naphthylamine hydrochloride solution was added but not sufficient to combine with the whole of the 2.7 acid present. By this means 3·53 g. of salt of m.p. 300°—302° were obtained. This showed it to be the slightly impure *β*-naphthylamine salt of the 2.7 acid. The remainder of the *β*-naphthylamine was then added as hydrochloride, whereupon 3·48 g. of the pure *β*-naphthylamine salt of the 2.7 acid, in the form of fine needles, m.p. 296°–298°, were obtained.

The 2.6 and 2.7 acids may also be separated by means of their aniline salts. For example, if just sufficient aniline hydrochloride is added to a solution of the potassium salts of the mixed acids to form the salt of the 2.6 acid present, the aniline salt of the 2.6 acid will separate in a practically pure condition. From the mother liquor, on evaporation, the familiar large, rectangular prisms of the potassium salt of the 2.7 acid can be obtained. *a*-Naphthylamine can also be used for the separation as the *a*-naphthylamine salt of the 2.7 acid will dissolve in its own weight of water at 100°, whereas the solubility of the corresponding 2.6 salt is only 4·72 parts per 100 at the same temperature.

The following salts were also prepared:—

m-Xylidine 2.7-naphthalenedisulphonate.—Colourless, long, flat plates from water, m.p. 292°—293°. It is readily soluble in hot water or alcohol but sparingly in the cold. Water at 20° dissolves 1·0 part per 100. 0·4012 g. required 15·2 c.c. $N/10$ NaOH= 100·4% theory.

m-Xylidine 2.6-naphthalenedisulphonate separated as a white colloidal precipitate and could not be obtained in crystalline form. Solubility in water at 20°, 0·35 part per 100. Does not melt below 360°. 0·6220 g. required 23·3 c.c. $N/10$ NaOH = 99·2% theory.

Cumidine 2.7-naphthalenedisulphonate.—An immediate white precipitate was obtained on mixing hot solutions of the base and acid. It is sparingly soluble in alcohol or water; m.p. 333°—335°. Solubility in water at 15°, 0·14 part per 100.

Cumidine 2.6-naphthalenedisulphonate Does not melt below 360°. Solubility in water at 15°, 0·06 part per 100.

ψ-Cumidine 2.7-naphthalenedisulphonate.—Fine white needles, very sparingly soluble in cold water but may be recrystallised from water or alcohol; m.p. 329°—330°.

ψ-Cumidine 2.6-naphthalenedisulphonate.—Very sparingly soluble in water but may be recrystallised from a large quantity of water. Does not melt below 360°. Solubility in water at 15°, 0·09 part per 100.

Benzidine 2.7-naphthalenedisulphonate. Prepared from benzidine hydrochloride and sodium 2.7-naphthalenedisulphonate, crystallised in elongated plates; not melting below 360°. It is very sparingly soluble in water or alcohol. 100 parts of the former only dissolving 0·11 part of the salt at 12°. In contradistinction to the previous salts, it, and the other diamine salts prepared, consist of only 1 molecule of base to one molecule of disulphonic acid. 0·2784 g. required 11·75 c.c. $N/10$ NaOH=99·6% theory.

Benzidine 2.6-naphthalenedisulphonate is precipitated immediately in white needles, practically insoluble in boiling water, on mixing boiling solutions of the base and acid. It does not melt below 360°. 0·5298 g. required 22·4 c.c. $N/10$ NaOH = 99·6% theory.

Tolidine 2.7-naphthalenedisulphonate separated in glistening elongated plates when recrystallised from a large quantity of water; its solubility in water at 20° is 0·13 part per 100.

Tolidine 2.6-naphthalenedisulphonate separated in elongated plates when recrystallised from water. It is more soluble in hot water than the corresponding benzidine salt, but its solubility in water at 15° is 0·09 part per 100. Neither this nor the preceding salt melts below 360°.

Dianisidine 2.7-naphthalenedisulphonate: grey, elongated plates on recrystallisation from water, m.p. 318°. 100 parts of water at 15° dissolve 0·08 part of the salt. 0·3950 g. required 14·7 c.c. $N/10$ NaOH=99% theory.

Dianisidine 2.6-naphthalenedisulphonate was very difficult to recrystallise and did not melt below 360°. Its solubility in water at 15° was 0·07 part per 100. 0·5944 g. required 22·2 c.c. $N/10$ NaOH=99·4% theory.

Dichlorobenzidine 2.7-naphthalenedisulphonate.—Recrystallised from water in cream-coloured needles which did not melt below 360°. Solubility in water at 15°, 0·08 part per 100.

Dichlorobenzidine 2.6-naphthalenedisulphonate, colourless needles very sparingly soluble in hot water, was obtained by extracting the crude product with boiling water. Does not melt below 360°. Solubility in water at 15°, 0·07 part per 100.

o-Anisidine 2.7-naphthalenedisulphonate recrystallised from alcohol in fine needles, m.p. 229°. It is very soluble in water and alcohol.

o-Anisidine 2.6-naphthalenedisulphonate is much less soluble in water than the corresponding 2.7 salt. It may be recrystallised from water, giving colourless needles, m.p. 295°. Solubility at 15°, 2·45 parts per 100.

p-Anisidine 2.7-naphthalenedisulphonate.—On recrystallisation from alcohol melted at 265°. Solubility in water at 15°, 1·54 parts per 100.

p-Anisidine 2.6-naphthalenedisulphonate.—Cream-coloured plates on recrystallisation from water; m.p. 326°. Solubility at 15°, 0·11 part per 100.

o-Phenetidine 2.6-naphthalenedisulphonate, m.p. 281° colourless needles Solubility in water at 15°, 1·14 parts per 100. 0·5342 g. required 19·1 c.c. $N/10$ NaOH=100·5% theory. We were unable to obtain the *o*-phenetidine salt of the 2.7 acid.

p-Phenetidine 2.7-naphthalenedisulphonate, greyish-brown crystals, which on recrystallisation from alcohol formed brown plates, m.p. 230°. Readily soluble in cold water.

p-Phenetidine 2.6-naphthalenedisulphonate separates immediately when hot solutions of the acid and the amine are mixed. Recrystallised from water in light brown plates, m.p. (decomp.) above 300°. Solubility in water at 13°, 0·13 part per 100.

m-Chloroaniline 2.7-naphthalenedisulphonate, from the sodium salt and *m*-chloroaniline hydrochloride, crystallised in fine coloured needles, m.p. 260°. Very soluble in hot water. Solubility in water at 15°, 0·97 part per 100.

m-Chloroaniline 2.6-naphthalenedisulphonate is much less soluble than that of the 2.7 acid and separates on mixing hot solutions of the hydrochloride of the base and the sodium salt of the acid. It crystallised from water in colourless plates which did not melt below 360°. Solubility in water at 15°, 0·12 part per 100.

p-Chloroaniline 2.7-naphthalenedisulphonate, fine white needles, m.p. 265°, by recrystallisation from alcohol. Solubility in water at 15°, 1·6 parts per 100. 0·5106 g. required 18·4 c.c. $N/10$ NaOH=97·8% theory.

p-Chloroaniline 2.6-naphthalenedisulphonate may be recrystallised from either 50% alcohol or water, yielding colourless plates which begin to melt with decomposition at 300°. Solubility in water at 15°, 0·14 part per 100.

m-Bromoaniline 2.7-naphthalenedisulphonate recrystallised from alcohol had m.p. 257°. Solubility in water at 15°, 0·29 part per 100.

m-Bromoaniline 2.6-naphthalenedisulphonate, white glistening leaflets from water, m.p. above 350° (decomp.). Solubility in water at 15°, 0·122 part per 100. 0·3274 g. required 10·35 c.c. $N/10$ NaOH=99·9% theory.

p-Bromoaniline 2.7-naphthalenedisulphonate, recrystallised from water melted at 266°. Solubility in water at 15°, 1·31 parts per 100. 0·5690 g. required 18·0 c.c. $N/10$ NaOH=100% theory.

p-Bromoaniline 2.6-naphthalenedisulphonate may be crystallised either from water or from 50% alcohol. White plates, which do not melt below 360°. Solubility in water at 20°, 0·133 part in 100. 0·3252 g. required 10·3 c.c. $N/10$ NaOH=100·1% theory.

1.2.4-Dichloroaniline 2.6-naphthalenedisulphonate white, glistening needles, m.p. 295°. Solubility in water at 10°, 0·46 part, and at 20°, 0·63 part per 100. 0·7402 g. required 24·0 c.c. $N/10$ NaOH=99·2% theory.

Monomethylaniline 2.6-naphthalenedisulphonate gave on recrystallisation from water grey needles, m.p. 272°. Solubility in water at 20°, 3·22 parts per 100. 0·3472 g. required 13·9 c.c. $N/10$ NaOH =100·5% theory.

The authors desire to acknowledge their indebtedness to Professor Heilbron for permission to carry out some of the experimental work in connexion with this paper in the Laboratories of the University of Liverpool.

THE USE OF THE LEAD CATHODE IN THE ELECTROLYTIC METHOD FOR THE DETERMINATION OF MINUTE QUANTITIES OF ARSENIC.*

BY T. CALLAN, M.Sc., PH.D., F.I.C.

The electrolytic method for the detection of minute amounts of arsenic depending on the formation of hydrogen arsenide at a metallic cathode and its subsequent detection by means of a mirror formed by passing the gas through a heated tube (Marsh-Berzelius) or by its action on mercuric chloride paper (Gutzeit) is now in very general use. The influence of the nature of the cathode was very exhaustively studied by Sand and Hackford,† who examined the relative sensitivity of various metallic cathodes, *e.g.*, platinum, lead, zinc, copper, etc., finally coming to the conclusion that lead was the most suitable metal for the purpose.

The lead cathode has subsequently come into common use and is generally regarded as being satisfactory. In the course of many hundreds of determinations of minute quantities of arsenic using lead cathodes, it has been

* Read at a meeting of the Manchester Section on Jan. 11, 1924.
† Chem. Soc. Trans., 1904, **85**, 1018–1028.

repeatedly noticed that the sensitivity of such cathodes is liable to vary very considerably from time to time. Thus a cathode which with 0·01 mg. of As_2O_3—a relatively considerable amount—gave a very decided stain on mercuric chloride paper when used in the apparatus subsequently described, after being in use for some days would often give a considerably weaker stain or even fail to give a stain with the same amount of added arsenic. Further, after standing for a few days such a cathode would in many cases recover its sensitivity whilst in others it failed to do so. Again if a number of new cathodes prepared from the same piece of lead wire were used regularly, whilst one might retain its sensitivity for weeks another might lose it after only a few days' use, but all would become eventually much less sensitive.

Owing to this irregular behaviour the continuous use of lead cathodes necessitates considerable precautions if the results obtained are not to be very misleading. Where a lead cathode is used only occasionally, however, no such difficulties have usually been experienced. With a view to elucidate the cause of such irregularities a series of experiments were undertaken. Sand and Hackford* showed that the addition of copper, iron, and certain other metallic salts caused serious loss of sensitivity of a lead cathode, and it was thought possible that the observed loss of sensitivity might be due to accumulated traces of such metals. A very considerable number of experiments were made, the following series being typical.

Three lead cathodes were used; two were made from new wire, the other having been in use at irregular intervals for about a year, and all were carefully cleaned and burnished. They were then used as cathodes in three electrolytic cells. The cell used was a modification of that suggested by Trotman (J., 1904, 178) and consisted of a glass tube prepared by cutting off the closed end of a test tube to give a cylinder approximately 3·5 × 11 cm. fitted with a bored rubber stopper and closed at the flanged end by a diaphragm of parchment paper secured by a rubber band. The cathode consisted of a length of lead wire about 35 cm. long and about 4 mm. in diameter, coiled into a spiral, and was brought directly through a gas-tight hole in the stopper to a screw connector to make contact with the source of current, which was taken from the lighting mains. In the majority of experiments the Gutzeit method of detecting the evolved hydrogen arsenide was employed, as this method lends itself to rapid repetition experiments and is sufficiently sensitive, 0·001 mg. As_2O_3 giving a definite stain on mercuric chloride paper. The evolved gases were passed through a glass tube containing, first, dry cotton wool, then cotton wool soaked in lead acetate solution and dried, and then passed through a glass tube 7 cm. long with a slight constriction at the bottom which would just accommodate a strip of mercuric chloride paper 4 mm. × 5 cm. Confirmative tests were made in a number of cases using the Marsh-Berzelius method. The current used in most experiments was 4—5 amps., the anode in every case being a piece of platinum foil welded on to a stout platinum wire. The electrolyte used was 15—20% sulphuric acid. Each cell gave a definite stain when 0·001 mg. of As_2O_3 was added. Further a strong stain was obtained with 0·01 mg. (a blank test immediately afterwards gave absolutely no stain), and finally a second addition of 0·001 mg. gave a definite stain. Hence the cathodes were not only sensitive but did not show any tendency to retain arsenic even when as much as 0·01 mg. was added.

The three cells were then run continuously for 12 hours using a current of 3—4 amps. At the end of this time 0·01 mg. of As_2O_3 was added to each cell. In each case only very weak stains were obtained corresponding to about one-fifth to one-tenth of the actual amount of arsenic added. Since no addition of any kind was made to the cells, the loss of sensitivity of lead cathodes after prolonged use cannot have been due to the gradual accumulation of traces of impurities from outside sources. The cathodes were then dipped into dilute nitric acid (1 : 2), washed in running water, and replaced in their respective cells. One cathode was then found to be sensitive, *i.e.*, a definite stain was obtained from 0·001 mg. and a strong stain from 0·01 mg., whilst the others were insensitive. The three cathodes were then again immersed in cold dilute nitric acid (1 : 1) for about 10 minutes, and washed in running water, and on testing all were found to have completely regained their original sensitivity. This recovery, however, was only temporary, as after only a few continuous experiments, and in some cases a single experiment, the cathodes rapidly became less sensitive but not all to the same extent. On standing overnight immersed in water they largely regained their sensitivity, but this also was only temporary, the cathodes becoming insensitive again after a brief use. In a similar series of experiments cathodes which definitely showed 0·002 mg. As_2O_3 failed to show that amount after being in use for two to three hours; they were completely reactivated by immersing in warm dilute nitric acid for a few minutes but not sufficiently long for any visible attack on the lead to be made. Cathodes which had become inactive owing to continuous use could only be revived to a small extent by vigorously brushing their surfaces.

Repeated experiments showed clearly that whilst a short treatment with cold or warm nitric acid would temporarily reactivate a lead cathode, on repeating the treatment several times, or if the cathode were left in the acid until it was vigorously attacked, the nitric acid had the opposite effect, *i.e.*, the cathode became quite insensitive although it possessed a brilliant metallic surface.

In one experiment as much as 0·03 mg. As_2O_3 was added to a cell containing a lead cathode which had been repeatedly treated with dilute nitric acid, but only a very small proportion of the arsenic was given off as hydrogen arsenide. On removing an aliquot portion of the cell solution and testing

* *loc. cit.*

by means of zinc and acid, the arsenic added to the cell was fully accounted for.

A number of lead electrodes were rendered insensitive by treating with hot dilute nitric acid until a vigorous gas evolution was obtained, making them the cathodes in the electrolytic cell for about one hour, and again treating with nitric acid. The cathodes after this treatment showed a bright metallic surface. Such electrodes only gave rise to a faint stain on mercuric chloride paper when as much as 0·01 mg. As_2O_3 was added to the cell. Similarly, when used as cathodes in the Marsh-Berzelius test only very weak mirrors were obtained with as much as 0·01 mg. As_2O_3. 1 c.c. of a 10% solution of cadmium sulphate was then added to the cells containing these inactive cathodes, when they immediately regained their full activity. When a similar amount of cadmium sulphate was added to cells containing cathodes which had become insensitive by continuous use for some hours, they also became more sensitive, but not *completely* so.

There appear, therefore, two ways in which lead cathodes may become insensitive.

(*a*) By prolonged use as cathode in dilute sulphuric acid solution. This is possibly due to the electrode becoming coated with a film of lead sulphate or oxysulphate, although in that case one would expect the electrode to be re-activated by treatment with a hot concentrated solution of ammonium acetate. Such, however, is not the case, but such inactivity may be removed by a mild treatment with dilute nitric acid.

(*b*) By removal of traces of metallic impurity from the surface of the cathode, giving a condition analogous to that into which the cathode can be brought by repeated treatment with nitric acid.

Inactivity due to this cause may be remedied by the addition of a trace of cadmium to the cell immediately prior to adding the solution to be tested. This would suggest that chemically pure lead is a much less efficient cathode than ordinary "pure" lead. It would also possibly explain why a lead cathode which, after only quite a short use, had become inactive, in many cases recovers its activity after allowing to rest for a few days, it being conceivably due to the formation of a superficial coating of pure, hence inactive, lead, which subsequently became of its normal "purity" by the migration of traces of foreign metals to the surface.

In spite of its limitations, however, the lead cathode undoubtedly remains an efficient and, if proper precautions are taken, reliable substitute for the expensive platinum cathode, which latter, indeed, also suffers from the liability to become insensitive under certain conditions (*e.g.*, roughening of its surface).

The abnormalities of the lead electrode described in the foregoing have only been observed where the same electrodes have been in continuous use for some hours or where a new electrode has deliberately been rendered insensitive by alternate treatment with nitric acid and use as a cathode.

In order to ensure that lead electrodes are always in a sensitive condition, it is strongly recommended that after each test they should be dipped for a few minutes in warm dilute nitric acid, removed immediately there is any sign of gas evolution, and well washed. Cathodes treated in this way have remained sensitive when used continuously for long periods. After treatment with nitric acid and washing, a trace of cadmium in the form of sulphate may be added to the cell, but this is not usually necessary unless the nitric acid treatment has been severe.

The procedure recommended by Sand and Hackford* in the case of new cathodes—that they be thoroughly scraped and cleaned by immersion in boiling strong nitric acid for 3 or 4 minutes—is not advisable, since this procedure generally results in reducing the sensitivity of the cathode to a considerable degree, and if prolonged may indeed render the cathode quite insensitive.

In conclusion, the author desires to express his thanks to Mr. J. D. Holiday, who has carried out a large number of experiments which have served to confirm the conclusions arrived at above, and also to Messrs. British Dyestuffs Corporation (Blackley), Ltd., in whose Central Analytical Laboratory the work was carried out.

LATHAM RESEARCH FELLOWSHIP.

The immediate purpose of the research to be described in the paper which follows is adequately stated by the author: but there is a further purpose obvious to critical observers, which is to establish working links between the systematic or "pure" chemistry of cellulose and the somewhat specialised development of the subject by way of physiology or biology and chemical industry. Whilst the latter have contributed important sections of exact science, the records of research work in this field express the general absence of the dominating *Leit motif*.

In the particular case of "oxycellulose," investigation has originated in the problems and exigences of industrial bleaching and dyeing operations with the restricted objective of establishing safe limits of oxidising treatment and recognition by qualitative tests of reaction beyond these limits. As a result there is an accumulation of literature which requires co-ordinating and re-editing from the critical standpoint of systematic chemistry. Thus the reactions of cellulose with oxidants are necessarily complex. Specific oxidation products of ultimate component groups are not easily identified: associated reactions of the order of interior migrations may be those of the complex, or take place in the proximate component group of C_6 or C_{12} dimensions. Hence the necessity of a methodical investigation of the oxidation of such compounds of known constitution and configuration, the results of which must afford a critical basis of re-examination of the literature of "oxycellulose," and also of "hydrocellulose."

The present research is modestly set forth by the author as only preliminary and not sufficiently exhaustive as a basis of theoretical discussion of the major questions. But attention may be called to certain results which on further verification and extension should furnish material of critical value for this purpose:—

(*a*) The addition of HOCl to β-glucosan as a reversible reaction: with increasing molecular proportion of the oxidant, the determination of hydrolysis to dextrose at ordinary temperatures.

(*b*) The production of lævulinic acid in the oxidation of sucrose by hydrogen peroxide.

It is in such methodical systematic study of reactions that results of significant importance are observed.

Thus the reactions under (*a*) would explain some particular aspects of the ordinary textile bleaching processes, but beyond this they are suggestive of a deductive basis of research of the fundamental problem.

The observations under (*b*) indicate an exceptionally labile equilibrium of the H.OH groups of the hexoses in presence of oxidants, tending to interior migrations, of the order of fermentation phenomena.

C. F. CROSS.

THE MECHANISM OF THE OXIDATION OF TYPICAL CARBOHYDRATES WITH HYDROGEN PEROXIDE AND HYPOCHLOROUS ACID.

BY JAMES CRAIK, M.A., B.SC., LATHAM RESEARCH FELLOW.

The problem of research which forms the subject of the present report was entrusted by Mr. C. F. Cross, F.R.S., to the author on his appointment as Latham Research Fellow in 1921. Stated briefly, the object of the work was to explore the action of simple oxidising media on selected carbohydrates with a view of gaining information as to the effect of these reagents in the technical treatment of cellulose. As a research of this nature must of necessity cover a wide field and its completion on scientific lines would demand the services of many workers for a period of years, it was considered advisable to limit the number of reagents employed and to study their effects as fully as possible in the time available.

The standard literature of the sugars contains numerous references to the oxidation of carbohydrates with acid and alkaline media. In particular, exhaustive studies have been made of the products formed on subjecting carbohydrates to the action of nitric acid, potassium permanganate and dichromate, silver oxide, and other common oxidisers.

J. U. Nef and his collaborators (Annalen, 1907, **357**, 214; 1910, **376**, 1; 1914, **403**, 204) spent nine years investigating the oxidation of the simple sugars in the presence of alkali and made a detailed study of the behaviour of carbohydrates dissolved in aqueous alkali hydroxides towards oxidising agents such as air, hydrogen peroxide, and the oxides of mercury, silver, and copper. It was ascertained (*ibid.*, 1914, **403**, 204) that the oxidation of 47 sugars resulted in the formation of carbon dioxide, formic, glycollic, oxalic, and *dl*-glyceric acids, four trihydroxybutyric acids, eight tetrahydroxyvaleric acids, and eight pentahydroxyhexoic acids. These results speak sufficiently for the complexity of the oxidation changes involved.

At an earlier date Cross, Bevan, and Smith had pointed out (Chem. Soc. Trans., 1898, **73**, 463) that only one reference (C. Wurster, Ber., 1887, **20**, 2631) could be found in the literature where the effect of hydrogen peroxide on the sugars had been tested, and this author dismissed the topic with the remark that glucose and cane sugar were remarkably stable towards this reagent. On the other hand, Fenton (Chem. Soc. Trans., 1894, **65**, 899; 1895, **67**, 48; 1896, **69**, 546) oxidised tartaric acid by means of hydrogen peroxide in the presence of ferrous salts with surprising results, and later applied the same reaction to the oxidation of polyhydric alcohols (*ibid.*, 1899, **75**, 1). As Cross, Bevan, and Smith stated in the paper already mentioned, these results disclose several points of interest with regard to the mode of action of hydrogen peroxide, more

particularly the oxidation of the residue —CH(OH)·CH(OH)— to —C(OH):C(OH)—. They therefore undertook the oxidation of a few typical carbohydrates by hydrogen peroxide in the presence of iron salts, but, apart from this development, there has been practically no further attempt to apply neutral oxidising agents to the carbohydrates.

As already explained, the purpose of the present work was to study in detail the mechanism of the oxidising action of hydrogen peroxide and hypochlorous acid on non-reducing sugars, with the ultimate intention of applying the results to starch and cellulose. These two reagents were selected as they are strong oxidisers and, as one of them is neutral and the other a weak acid, they are unlikely to cause profound molecular alteration in the sugars employed. In addition, both reagents are applied technically to cellulose.

In the present work the oxidation reactions were studied under conditions in which the ratio of the available oxygen atoms to each C_{12} unit in the carbohydrate was either $\frac{1}{2}$, 1, 2, or 5. In addition to non-reducing sugars, it was found necessary to use controls in which dextrose and lævulose were used. The progress of the reactions was traced :—

(1) Polarimetrically,
(2) By determining the rate of disappearance of the available oxygen,
(3) By determining any change in acidity,
(4) By determination of variations in the reducing action on Fehling's solution,
(5) By the action of phenylhydrazine acetate at 20°, 60°, and 100° on the products of the oxidation,
(6) By isolation and identification of the individual products.

Considering the ultimate object in view, the oxidation was allowed to proceed at ordinary temperature in all cases.

It was thought advisable to start with saccharides of simple and known constitution, and for this reason sucrose was selected as a test substance in view of its non-reducing properties. In addition the possibility was open that this compound, containing, as it does, one γ-sugar residue in combination, would possess the property of combining directly with one atom of oxygen without molecular rupture (Irvine, Fyfe, and Hogg, Chem. Soc. Trans., 1915, **107**, 524). In addition, lactose and maltose were selected for experiment as representative of reducing disaccharides differing in essential structure from sucrose.

A survey of the results taken in conjunction with recent developments in the chemistry of starch and cellulose quickly showed that they had no direct bearing on the oxidation of cellulose, and it was deemed advisable to introduce another series of test substances. The oxidation of β-glucosan was accordingly undertaken as, although this component is not present in cellulose, it bears, as an anhydride possessing the formula $C_6H_{10}O_5$, a closer resemblance to the group of polysaccharides than do any of the sugars proper. In addition, the compound is now the most accessible of the anhydro-sugars and may be employed in large-scale experiments. The principal results obtained in this section of the work are now described.

The action of hydrogen peroxide on disacchari
Sucrose, maltose, and lactose.

In the absence of a catalyst the above disacchar were stable at ordinary temperatures towards hy gen peroxide, but in the presence of ferrous sulpl oxidation proceeded rapidly even at room temp ture. In the case of sucrose, where the ratio of av able oxygen was over $\frac{1}{2}$ atom per C_{12} unit, it ascertained that the oxidising agent attacked of the primary alcoholic groups and converte into the carboxyl group. The acid thus for effected inversion of the remaining sucrose and scission products then underwent independent ox tion, to give a complex series of acids. This deve ment of free organic acid increased rapidly as amount of active oxygen was increased. Formic acetic acids were then produced in quantity, there was no evidence of the presence of gluc acid, the molecular rupture giving essentially a with two and three carbon atoms in the ch Judging from the action of phenylhydrazine on products of the change, lævulinic acid was prese a surprising result considering the conditions.

The precipitates yielded by phenylhydrazine somewhat indefinite and consisted mainly of phe glucosazone together with mixed hydrazides organic acids, the separation of which was diffi The combined results of the experiments prove

1. If direct addition of oxygen to the suc molecule takes place the product is not neu but acidic.
2. The lævulose residue in sucrose, although o γ-type, does not undergo oxidation in the s manner as γ-methylglucoside.
3. The formation of free acid precedes hydrol
4. Once hydrolysis commences, the oxida becomes rapid and is ultimate.

No part of the evidence obtained seems to have bearing on cellulose problems beyond the fact any reaction which liberates a reducing sugar in presence of hydrogen peroxide leads to rapid dest tion of the sugar molecule.

In pursuing a parallel series of experiment maltose and lactose it was apparent that the rea attacked the reducing group of the sugar with formation of maltobionic acid and lactobionic respectively. As in the case of sucrose, these products effected the hydrolysis of the paren saccharides, and oxidation of the fragments ens Such changes are notoriously complex, and hydr peroxide was abandoned in favour of hypochlo acid, as the possibility was not excluded that reagent might act in an entirely different mann

The action of hypochlorous acid on the disacchar
Sucrose, maltose, and lactose.

In the principal experiments the amount of h chlorous acid was adjusted so that one atomic pr tion of oxygen was available for each C_{12} unit c carbohydrate. As before, the disaccharides ployed were sucrose, maltose, and lactose. these bioses no organic acids were formed as pro of oxidation, the result offering a sharp contra that obtained with hydrogen peroxide. Sucros

narkably stable towards hypochlorous acid; in t, when the oxidation was carried out in the presce of a base to neutralise the hydrochloric acid med by the decomposition of the oxidising acid, ·6% of the original weight of sucrose persisted after mplete utilisation of the hypochlorous acid. Even the absence of a base reaction was comparatively w and no acidity was developed. The final value the specific rotation of the oxidised solutions did t coincide with that calculated from the compoion of the residual sugar as determined from the pper-reducing power. Similar results were obtained th maltose and lactose, the same optical lag being orded in all the experiments. In the case of tose the specific rotation actually diminished in ace of increasing.

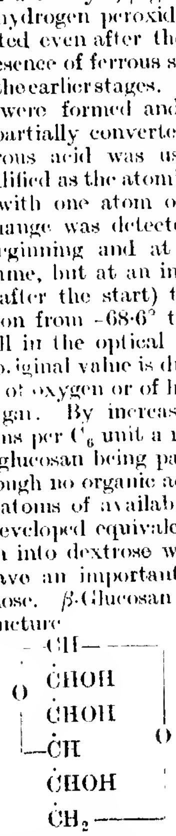
In view of these results the general conclusion may drawn that hypochlorous acid acts on the disacarides through the preliminary formation of an lditive compound. Attempts to isolate such a mpound were naturally unsuccessful, but the comned physical evidence is strongly in favour of its istence.

he action of hydrogen peroxide and hypochlorous acid on β-glucosan.

In the absence of a catalyst, β-glucosan proved to stable towards hydrogen peroxide, practically no ange being detected even after the lapse of several ys, but in the presence of ferrous salts reaction was pid, especially in the earlier stages. Both volatile and on-volatile acids were formed and simultaneously e glucosan was partially converted into dextrose.

When hypochlorous acid was used the reaction s profoundly modified as the atomic ratio of oxygen reased. Thus, with one atom of oxygen per C_6 it, very little change was detected. The specific tation at the beginning and at the end of the tion was the same, but at an intermediate stage out two hours after the start) the value of $[\alpha]_D$ owed a diminution from $-68·6°$ to $-55·2°$. In all obability this fall in the optical activity followed a return to the original value is due to the tempory addition either of oxygen or of hypochlorous acid the anhydro-sugar. By increasing the ratio of ygen to two atoms per C_6 unit a remarkable result s obtained, the glucosan being partially converted to dextrose although no organic acids were formed. nally, with five atoms of available oxygen per C_6 it acidity was developed equivalent to $N/20$ acid, d the conversion into dextrose was accelerated.

These results have an important bearing on the idation of cellulose. β-Glucosan has been shown possess the structure

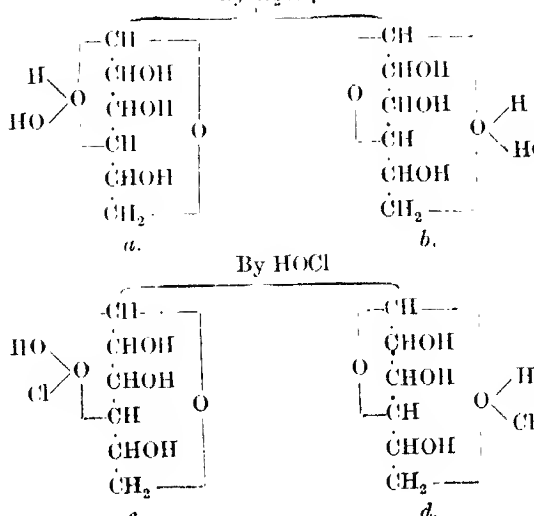


Even if Pictet's views as to the relationship of β-glucosan to cellulose are not accepted, the former compound must be regarded as being closely related to the unit of the polysaccharides. Now, glucosan is not readily hydrolysed, even on heating with sulphuric acid, to regenerate dextrose, yet the results of the present research have shown that in the absence of stable acids the anhydro-ring can be opened out at ordinary temperatures, and that dextrose is then formed. This points clearly to the idea of a preliminary addition of hypochlorous acid to one of the ring-forming oxygen atoms (probably that connecting the terminal carbons). If this view be correct, a necessary consequence is that the oxidation of β-glucosan should follow an entirely different course when occasioned by oxidising agents which do not admit of molecular addition. The point has been established in the course of a parallel research, carried out by Irvine and Oldham, who subjected glucosan dissolved in methyl alcohol to the action of silver oxide. Essentially three acids are formed containing respectively 3, 4, and 5 carbon atoms in the chain, one of these compounds being a ketonic acid containing two hydroxyl groups. In this type of oxidation no dextrose is liberated, and the molecule suffers progressive disruption.

Action of hypochlorous acid on starch and cellulose.

The most important result disclosed in the experiment just described is that dilute hypochlorous acid is capable of effecting at ordinary temperatures the hydrolysis of n-saccharides or anhydro-sugars. Emphasis must be laid on the example of β-glucosan, which requires prolonged boiling with 4–5% sulphuric acid in order to open the anhydro-ring, yet undergoes the same change at 16° in the presence of 1·8% hypochlorous acid. Both reagents effect hydrolysis, yet the mechanism of the change cannot be identical in both cases. The opening of a ring compound is generally explained by preliminary addition, and applying this principle to the hydrolysis of glucosan, we have the alternatives :—

By H_2SO_4



Types *a* and *c* may reasonably be excluded as the product is the butylene-oxide form of dextrose; *b* may be transformed directly into the reducing sugar, but *d* can undergo this reaction only after secondary changes involving the liberation of oxygen. It is highly significant that in the presence of one molecular proportion of hypochlorous acid, glucosan is stable.

Evidently support would be lent to the above views if it could be shown that polysaccharides behaved in the same manner as glucosan and underwent hydrolysis with low concentrations of hypochlorous acid. In the case of starch this has been confirmed, and as much as 80–90% of the compound is converted into a mixture of soluble dextrins, maltose, and dextrose after 48 hours' action in the cold. The properties of cellulose render a strictly comparative study difficult, and the experiments carried out on this polysaccharide could not be extended beyond the point of ascertaining the concentrations of hypochlorous acid at which: (1) oxycellulose, (2) oxalic acid first make their appearance. The results, which are given in the experimental part, are capable of considerable theoretical discussion, but this would be premature in the case of a preliminary research of this nature.

EXPERIMENTAL.

The action of hydrogen peroxide on sucrose.

(*a*) *Without a catalyst.*—Typical experiments only are quoted. The sucrose solution used in these experiments was $M/6$ (5·7%). Three experiments were carried out with the ratio of available oxygen contributed by the hydrogen peroxide in the proportion of 1, 2, and 5 atoms per C_{12} unit. There was no rise in temperature on mixing; the optical activity remained constant; no action on Fehling's solution was developed and no organic acids were formed. It was therefore evident that sucrose was quite stable to hydrogen peroxide in the absence of a catalyst.

(*b*) *With a catalyst.*—Fenton and Jackson (Chem. Soc. Trans., 1899, **75**, 1) oxidised polyhydric alcohols with hydrogen peroxide in presence of ferrous sulphate; they used the catalyst in the proportion of 1/10 atom Fe'' as crystalline ferrous sulphate per molecule of the alcohol. Similar ratios were used in the present work, the concentration of the sucrose solution being $M/6$. The oxidations were studied under conditions in which the oxygen ratio per C_{12} unit was either ¼, ½, 1, or 2. Unfortunately, owing to the turbidity and brown colour of the solution, caused by the oxidation of the ferrous salt, it was impossible to study the progress of the reaction polarimetrically. The disappearance of active oxygen and the development of acidity were determined by direct titration. When the decomposition of the hydrogen peroxide was complete, a portion of the liquid was evaporated to dryness under diminished pressure at a bath temperature of about 35°. On extracting the residue with 80% alcohol at the boiling point and distilling the solvent in a high vacuum, a syrup was obtained, the copper-reducing power of which was determined before and after hydrolysis.

As these experiments were carried out on e similar lines, it is most convenient to displa results in tabulated form.

Ratio of oxygen in H_2O_2 per C_{12} unit	¼	½	1	
Rise in temperature (on mixing).—

½	80·0
1	80·3
2	95·72

The oxidation of maltose with hydrogen peroxide i presence of ferrous sulphate.

(*a*) *One atom available oxygen to one molecule mal ose.*—100 c.c. of maltose solution containing 5·7 g of pure maltose were mixed with 5 c.c. of ferrou sulphate solution containing 0·463 g. of crystallin ferrous sulphate; 25 c.c. of hydrogen peroxide solu

ı (0·266 g. available oxygen) were added and the :ture was well stirred with a thermometer. The ıperature rose from 16° to 19°. An examination intermediate stages showed :—

Time in min.	Acidity.	Disappearance of available oxygen, % of total.
10	$N/13{\cdot}7$	40 0
90	$N/10\ 4$	98 3
120	$N/10\ 3$	99 1
150	$N/10{\cdot}3$	100 0

b) *Two atoms available oxygen.*—On mixing the ıtions of maltose and hydrogen peroxide the nperature increased 3°, and after 90 minutes m the start there was another rise from 14·5° iginal temperature) to 30°. The figures shown low were recorded :—

Time in min.	Acidity.	Disappearance of oxygen, % of total.
10	$N/18\ 5$	18 1
30	$N/12\ 3$	42 3
90	$N/8$	98 1
120	$N/7\ 9$	99 3
150	$N/7\ 85$	100 0

(c) By decreasing the amount of available oxygen ½ atom the rate of the reaction was :—

Time in min.	Acidity.	Disappearance of oxygen, % of total.
10	$N/23$	82 8
30	$N/21\ 27$	92 18
90	$N/21\ 4$	93 75
120	$N/10{\cdot}7$	94 53
150	$N/19\ 6$	100 0

In all cases the residual products were isolated ter removal of volatile acids and inorganic salts. ıe syrup obtained was tested with Fehling's solution fore and after hydrolysis. A comparison of the o copper values showed :—

Atomic proportion of oxygen.	Reducing power before hydrolysis % of that of dextrose
½	69 0
1	79 93

idation of disaccharides with hypochlorous acid.

The hypochlorous acid was prepared by an unpubhed method devised by Principal Irvine which lded a solution free from chlorine and more ghly concentrated than that obtained by ordinary ocesses.

The progress of the oxidation was traced larimetrically in addition to the controls employed th hydrogen peroxide.

(a) *The action of hypochlorous acid on sucrose.*—this series of experiments 1 atom of available ygen was used per C_{12} unit. 50 c.c. of sucrose lution (5·7%) were mixed at room temperature th 50 c.c. of hypochlorous acid solution (0·87%). e reaction was slow, 1 atomic ratio of oxygen uiring almost 24 hours for complete utilisation. organic acids were formed, the acidity developed ng exactly equivalent to the hydrochloric acid m the decomposition of the hypochlorous acid ed. There was a steady decrease in the value the specific rotation as shown below :—

Time in hours from start.	$[\alpha]_D$.	Disappearance of active oxygen, % of total.
0	+66 6°	3 44
2	+61·7°	—
4	+55·7°	68·7
7·5	+54 7°	88·0
22	+54 0°	100·0

On isolating the residual sugar after all oxidation had ceased, the copper value was 23·3% of that obtained on complete hydrolysis. The specific rotation calculated on this hydrolysis should have been $[\alpha]_D$ +46·4°. The actual drop in optical activity was from $[\alpha]_D$ +66·6° to +54°.

(b) *The action of hypochlorous acid on lactose.*—In the following experiments 1 atom of available oxygen was allowed per C_{12} unit. 50 c.c. of $M/6$ lactose solution were mixed with 50 c.c. of hypochlorous acid (containing 0·87% HOCl). The reaction proceeded very slowly, extending over a period of 48 hours. During this time no organic acids were formed and the specific rotation changed from +52·5° to +47·6°.

Time in hours from start.	$[\alpha]_D$.
0	+52 5°
2	51 5°
6	51 3°
20	51 3°
44	49 6°
48	47 6°

On isolation of the residual sugar, analysis gave a copper-reducing value of 81·9% of that determined after hydrolysis. This partial hydrolysis of lactose should give the optical change $[\alpha]_D$ +52·5° to +66·6° in place of +47·6°.

(c) *Action of hypochlorous acid on maltose.*—For each C_{12} unit, 1 atom of available oxygen from the hypochlorous acid was used. The solutions were mixed as before in the above proportions. The reaction was extremely slow, the maltose reacting completely with the hypochlorous acid only in 80 hours. No organic acids were found as products of the oxidation. Polarimetric readings showed a gradual decrease from $[\alpha]_D$ +134° to +123·5°.

Time in hours.	$[\alpha]_D$.
0	+134°
24	+125 9°
48	+119 6°
80	+123 5°

The total product was isolated and the reducing power determined before and after hydrolysis, the ratio being 69·0%. Here again the analytical results are not consistent with the optical activity, and the general conclusion may be drawn that the oxidising agent acts on the sugar through the preliminary formation of an additive compound.

Oxidation of β-glucosan.

(a) *The action of hydrogen peroxide on β-glucosan.*—(1 atom of available oxygen in hydrogen peroxide per C_6 unit). In the absence of a catalyst hydrogen peroxide gave negative results. After standing for seven or eight days only slight traces of acidity were developed and over 50% of the hydrogen peroxide still remained. In presence of ferrous sulphate the reaction proceeded fairly rapidly.

60 c.c. of a 2·7% solution of glucosan, containing ferrous sulphate, were mixed with 60 c.c. of hydrogen peroxide solution (0·266% available oxygen). The reaction extended over a period of 24 hours. The acidity developed was equivalent to $N/23$ acid, almost half of which was due to volatile acids. The

progress of the reaction can be followed from the table below:—

Time.	Acidity	Disappearance of oxygen. %
10 min.	$N/40$	45·5
40 ,,	$N/38·4$	51·0
60 ,,	$N/37$	57·8
16 hours	$N/27·4$	94·3
20 ,,	$N/25·9$	95·1
21 ,,	$N/25·3$	96·2
24 ,,	$N/23·2$	100·0

A portion of the liquid was evaporated to dryness under diminished pressure. The residue was boiled under a reflux condenser with 80% ethyl alcohol, the solution being filtered and evaporated to a syrup in a high vacuum. This residual product reduced Fehling's solution, and the copper values determined before and after treatment with dilute acid showed that the oxidation had yielded: dextrose, 10·7 parts; unchanged glucosan, 48·3 parts; non-volatile acids, 41·0 parts.

(*b*) *The action of hypochlorous acid on β-glucosan.*—Owing to the prolonged time necessary for the preparation of pure hypochlorous acid, it was decided to utilise bleaching powder as the source of the oxidising agent. A good specimen of bleaching powder was shaken for a considerable time with distilled water. After standing for a few hours the insoluble calcium salts were filtered off, and the calcium hypochlorite present in the filtrate was determined by analysis. The solutions of the carbohydrate and calcium hypochlorite were mixed in the desired proportions and the hypochlorite was then decomposed by blowing carbon dioxide through the solution from time to time until the oxidation was complete.

(1) 1 *Atom of available oxygen in hypochlorite per* C_6 *unit.* 100 c.c. of a 2·7% solution of β-glucosan were mixed with 100 c.c. of hypochlorite solution, containing available oxygen in the above proportions. There was no variation in temperature on mixing or during the reaction. The total disappearance of oxygen extended over a period of 20 hours, and during that time no acidity was developed. The optical activity underwent the following change:—

Time, hours.	$[\alpha]_D$.
0	−68·6° start
2	−55·2° minimum
24	−68·6° final value

On isolating the residual products, a syrup was obtained which did not reduce Fehling's solution. This was to be expected, since the final value of $[\alpha]_D$ was −68·6°.

(2) 2 *Atoms of available oxygen per* C_6 *unit.* The solutions were well mixed and carbon dioxide was blown through the solution from time to time. The polarimetric readings indicated a fall in the specific rotation from −68·6° to −43·7° after 27 hours.

Time, hours	$[\alpha]_D$.
0	−68·6°
6	−51·1°
24	−42·9°
27	−43·7°

The residual products when isolated, showed a reducing action on Fehling's solution. On the basis of titrations before and after hydrolysis the composition of the mixture was: dextrose, 1 part; unchanged glucosan, 3·44 parts.

(3) 5 *Atoms of available oxygen provided for ea* C_6 *unit.* In these proportions the reaction proceed more vigorously. Within 10 minutes of mixing t temperature rose from 16° to 39°. Acidity w developed to the extent of $N/20$ acid. Polarimet readings were impossible during the intermedia stages owing to the turbidity of the solution a evolution of gas. At the end of 50 hours, when t oxidation ceased, the specific rotation had chang from $[\alpha]_D$ −68·6° to −27°.

100 c.c. of the solution were neutralised a evaporated to dryness; the residue was boiled unc a reflux condenser with alcohol, filtered, and evap ated under diminished pressure to a syrup whi reduced Fehling's solution. The copper reduci value found after boiling with dilute acid, show that a 30·2% conversion of glucosan to dextrose h taken place during the oxidation: dextrose, 1 pa unchanged glucosan, 3·3 parts.

The action of hypochlorous acid on starch.

(*a*) 0·87 *g. of hypochlorous acid* (*from calcium hy chlorite*) *per* 2·7 *g. of starch.* A solution of 5·4 g. Japanese potato starch in 100 c.c. of water was mix with 100 c.c. of hypochlorite solution, the conc tration of which was adjusted to give the abo proportion of available oxygen. The reaction w very slow, the hypochlorous acid being utilised or after the lapse of several days. On examining t solution polarimetrically, it was found to be dext rotatory, the value of α increasing as the availal oxygen was used. Only a very slight acidity w observed at the end of the reaction.

When all oxidation had ceased, 100 c.c. of t solution were evaporated to dryness under diminish pressure. The residue was boiled under a refl condenser with alcohol, filtered, and the alcoho solution evaporated to a syrup under reduced pressu From 2·7 g. of starch the syrup obtained in this w weighed 1·9581 g., showing that about 75% of t starch had been transformed into soluble produc The syrup reduced Fehling's solution, the cop reducing power being 33·7% of that obtained af boiling with dilute acid.

Precipitates produced by the action of phen hydrazine, as was the case in the earlier stages of t work, were somewhat inconclusive, but indicat that maltose, together with its oxidation produc was present.

(*b*) 1·74 *g. of hypochlorous acid* (*from hypochlor solution*) *per* 2·7 *g. of starch.* In these proportic over 90% of the starch reacted. The results w very similar to those quoted above, and examinati of the residual syrup indicated a copper reduci power equal to 90% of that obtained on comple hydrolysis.

The action of hypochlorous acid on cotton cellulose.

(1) 0·87 *g. of hypochlorous acid* (*from calcium hy chlorite solution*) *per* 2·7 *g. of cellulose.* Cott cellulose was found to be remarkably stable to hy chlorous acid when present in the above proportic and when the concentration was 0·87 g. of hy chlorous acid per 100 c.c. After 48 hours the hy chlorous acid was exhausted, but an examinati

the oxidation products showed that 86% of the llulose still remained intact. Only traces of oxy-llulose and oxalic acid were found.

(2) *1·74 g. of hypochlorous acid per 2·7 g. of cellu-se (concentration of acid, 1·74 g. per 100 c.c.).* Even these proportions the change was not exten-ve, although the formation of oxycellulose and alic acid was increased. The weight of the residue om 2·7 g. of cellulose was 2·0711 g., showing a loss weight of 23·2%.

(3) *4·35 g. of hypochlorous acid (from hypochlorite lution) per 2·7 g. of cellulose.* 2·7 g. of cellulose ere mixed with 100 c.c. of acid of 4·35% concentra-on. At the end of the reaction, which extended er almost 48 hours, the residue and filtrate were amined; 20 c c. of the filtrate gave on evaporating dryness, 1·9120 g. of residue. Calcium and lorine were determined in another 20 c.c., the lts being: Ca, 0·69 g; Cl, 0·80 g. Difference, 41 g. No volatile acids were found as products the oxidation.

From 2·7 g. of cellulose the residue weighed 1·9532 g owing a loss in weight equivalent to 27·66%. The sidue in this case was not fibrous but amorphous. was partially soluble in alkaline solution (to the tent of 88·6%). From this alkaline solution the ycellulose could be reprecipitated by means of ids, salts, or alcohol. It gave no blue coloration ith iodine in potassium iodide. Concentrated lphuric acid attacked and dissolved it giving a dark rown solution. It reduced Fehling's solution on oiling.

University of St. Andrews.

DEHYDRATION OF ALCOHOL BY MEANS OF GLYCERIN.*

BY EDMUND KNECHT AND ERIC FRANK MULLER.

It is well known that pure glycerin readily takes up a certain proportion of water which it retains tenaciously at the boiling point of water and even beyond that temperature. It was considered of interest to ascertain whether this property might be utilised for the dehydration of ordinary alcohol, with a view of working out a rapid and convenient process for the preparation of "absolute" alcohol.

In a preliminary experiment some ordinary alcohol (of about 95% strength) was mixed at random with glycerin and distilled from a water bath; pure alcohol came over.

In order to ascertain to what extent pure alcohol is retained by pure glycerin at 100°, a quantitative distillation was carried out. Absolute alcohol (40 g.) mixed with pure glycerin (10 g.) was distilled from a water bath until no more liquid came over, and the distillate collected in a flask provided with a loosely-fitting cork; 37·8 g. of alcohol were recovered, so that 2·2 g. had remained in the glycerin, equivalent to 5·5% of the alcohol taken. By heating the residue in the flask to 180°, a further recovery of 2·15 g. of alcohol was effected, so that the loss was practically nil. (Correction was made in this and other instances for the volume of alcohol vapour remaining in the distillation flask.) This result might appear to indicate that a process based upon the use of glycerin as a dehydrating agent would result in a loss of alcohol if the distillation were carried out on the water bath only. It was shown, however, that if the alcohol contains water the latter appears to be selectively absorbed by the glycerin. This was seen to occur on distilling a mixture of 89·80 g. of alcohol, 9·93 g. of water, and 23·91 g. of glycerin from a water bath: the distillate collected between 78° and 79° weighed 88·77 g., which is equivalent to a 98·8% recovery.

In a further experiment, a litre of commercial alcohol mixed with 24% (by weight) of glycerin and distilled from a water bath gave a yield of 93% of alcohol which came over between 78° and 78·5° and corresponded to a 98% product.

The distillate, tested for glycerin, gave a negative result providing that no more was collected after the thermometer (bulb in vapour) had reached 80°. Beyond this temperature traces of glycerin are liable to pass over; at 85° an appreciable amount (0·05%) was found in the distillate.

From the results of these preliminary trials it was inferred that a single distillation was not sufficient to yield a completely dehydrated product when employing what was considered to be a reasonable amount of glycerin, *i.e.*, an amount which would not unduly depress the final yield. The amounts of glycerin suitable for a first distillation were roughly gauged as follows:—

For 10% water present, 25% glycerin by weight
5% „ „ 20% „ „ „
2% „ „ 15% „ „ „

Double distillation.—By following up the first distillation by a second, in which less glycerin is added, it was found possible to remove almost the whole of the remaining water, as is shown by the following examples:—

50 c.c. of commercial alcohol distilled with 10 c.c. of glycerin gave a yield of 46 c.c. of alcohol, b.p. 78°—79°. The 46 c.c. of this partially dehydrated product were then mixed with 7 c c. of glycerin and redistilled, the distillate, amounting to 42 c.c., being collected up to 78°. The final product showed b.p 77·8°—77·9° and *d* 0·7900

In a further trial 150 c.c. of commercial alcohol on being double distilled with glycerin gave a yield of 126 c.c. of alcohol, b.p. 77·8°—77·9°, d^{15} 0·7950, representing a yield of 84%.

It is thus evident that the proposed method gives a satisfactory product with very little trouble and in sufficiently good yield to be of some practical value in the laboratory. The action of the glycerin, unlike that of burnt lime, is instantaneous, and after adding it to the alcohol distillation can be proceeded with at once.

In testing the final products, the boiling point and specific gravity only were relied upon, as it was

* Read at a meeting of the Manchester Section, on Feb. 1, 1924.

Journal of the Society of Chemical Industry.

found that the usual copper sulphate test was too slow to allow of its convenient application to alcohol of high concentration. Incidentally this test was tried on a series of mixtures of alcohol and water, and the results are briefly stated below. They show the time which was found to be required for the first indication of a blue tinge in the copper sulphate.

Water % by weight	0·6	1·24	1·72	2·44	2·73	3·43	6	12
Time in hours	120	26	8	6	5	4	2·5	0·4

The copper sulphate used for the purpose was prepared by precipitating a concentrated solution of ordinary copper sulphate with alcohol and heating the resulting crystalline powder in an air oven to 180°. The tests were carried out in small, well-stoppered glass bottles.

Various alternative modes of procedure have suggested themselves for carrying out the dehydration, and have been tried with more or less success.

One of these, which was quite obvious, was to effect the distillation of the mixture of alcohol and glycerin in a small distillation flask, the mixture being run in continuously through a tap funnel. The result obtained was satisfactory, but it cannot be said that this procedure offers any advantage in the ordinary way.

In a second modification it was sought to effect the whole rectification in a single operation. To this end, the vapour distilling over from a mixture of commercial alcohol and glycerin was caused to pass through a series of three narrow cylindrical wash-bottles, each of which contained a small amount of glycerin. The wash-bottles were contained in a water-bath heated to 78°, and the vapour after leaving the third and last bottle passed directly into the condenser. This modification gave a satisfactory result in that an alcohol passing over entirely at 78° was obtained in a single operation.

A third modification was to cause the vapour issuing from the mixture of alcohol and glycerin to pass through an inverted upright condenser filled with glass beads, over which glycerin was allowed to trickle at the rate of about one drop in five seconds. The tube containing the glass beads was kept hot by blowing a current of steam through the outer jacket of the condenser. The vapour thus dehydr condensed in the ordinary way. This although somewhat more complicated than tl gave a very satisfactory result, in that co alcohol was found to give a yield in a single c of 85% of a product showing d^{15} 0·7959.

The products obtained did not in any ca 100% purity, though it is easy to effect by the a dehydration yielding a 99·5% product. A it is not improbable that further dehydratio be effected by the use of a large excess of g it would seem preferable to resort to the use o lic calcium for the removal of the last traces o

The cost of the process for laboratory use is of the way as far as the glycerin is concerned, 1 of glycerin is sufficient to dehydrate 3 lb. of a this being equivalent to an additional cost of 4 per pound on the latter. On the other hand are compensating advantages in the great re in the time required and in greater cleanliness operations. In case the process were to be em on any extended scale it should be possible to re ate the glycerin in a separate plant.

Chemical Department,
Manchester College of Technology.

The work detailed in this paper was carrie at the Manchester Municipal College of Techn during June and July, 1923, and the paper was w up in August of the same year. The paper announced in the syllabus of the Manchester Se in October, 1923. In the interval between dates and the time of reading the paper, Ma published an elaborate account of his process fo commercial dehydration of alcohol (Chimie et In trie, Oct., 1923), which is based upon practically same principle as our own. The points of differ are: (1) That whereas Mariller's process is inte for large-scale work, ours was originally only inte for laboratory use. (2) In our process, the glyc is added to the alcohol, though we have also opera subsequently by dehydrating the vapour. (3) Mar makes no mention of the possibility of the prese of glycerin in the distillate, whereas we have fo that unless certain conditions are observed distillate will be contaminated. Our paper c tains, in addition, some account of the copper sulph test for determining the strength of alcohol.

UXITE AS A REFINING AGENT FOR PETROLEUM DISTILLATION.*

. E. DUNSTAN, D.SC., F.I.C., F. B. THOLE, D.SC., F.I.C., AND F. G. P. REMFRY, D.SC., A.I.C.

rom the very earliest times practitioners in the of refining have recognised the remarkable acity possessed by certain substances, particularly rcoal and various porous earths, for selectively orbing from natural products in common use ces of impurities which impair the colour, odour, flavour of the material. Among the many sub- nces which possess these absorptive properties high degree are bone charcoal, specially prepared etable charcoals, fuller's earth, floridin, certain ys of Californian and Japanese origin, silica, and mina. Some of the most effective of these belong the category of inorganic gels which have been rmed by the dehydration of a hydrogel such as icic acid or aluminium or ferric hydroxides.

A very cheap and convenient gel is the mineral uxite, which is a soft rock composed principally hydrated aluminium and ferric oxides associated ith varying amounts of silica, lime, titania, and gnesia. The mineral in its natural state has no sorptive qualities, but by roasting to an appro- iate temperature most of the water of combination expelled, whereby the peculiar porous structure developed upon which the refining efficiency epends. Careful study has proved the interesting ct that the chemical composition of a bauxite as no bearing on its effectiveness as a refining agent; auxites of very dissimilar composition will give entical results on the refinery, whilst successive mples with identical chemical analyses may be ntirely different in behaviour (3rd Report of the ritish Association Committee on Colloids, p. 91 *seq.*).

As a refining agent for petroleum, bauxite has narked advantages over many other substances hich also possess adsorptive properties. The size f the pores and nature of the surface happen to be ust appropriate for the purpose in view, namely, he adsorption of the organic sulphur compounds and colouring matter which it is desirable to remove rom petroleum distillates. It is cheap, can be used n granular form (which obviates the need for filter presses and accelerates the filtration process), and an be recovered indefinitely (apart from loss due o disintegration). Though it is now known that auxite when suitably prepared has the power of electively adsorbing both colouring matter and ulphur compounds, the latter property is of com- paratively recent discovery. The use of this material or decolorising kerosene and paraffin wax, however, was adopted by the Burmah Oil Company many ears ago.

The procedure used at the Burmah refinery was as follows:—The bauxite was placed in cylindrical filters measuring approximately 8 ft. by 2 ft. 6 in., and holding about 1 ton, and the kerosene or wax was filtered through until the colour of the outcoming oil was no longer up to the required standard. The spent bauxite was then extracted with benzine in a Merz extractor by continued percolation (after the manner of the Soxhlet apparatus) until no further removal of the adsorbed coloured compounds could be brought about.

The extracted bauxite, after removal of adherent benzine, was then passed through a vertical furnace into which it was dropped from a hopper at the top and fell from one sloping firebrick plate to another until it passed out at the bottom. During the whole period of its passage it came into direct contact with the hot gases (mixed with excess of air) from an oil burner, which oxidised any carbon- aceous matter or hydrocarbons remaining after the extraction. It was then cooled as quickly as possible, when it was seen to be as clean and bright as new bauxite. For decolorising paraffin wax, the filters were steam-jacketed in order to keep the wax in a molten state.

When it became necessary to purify kerosene which contained both coloured matter and odoriferous sulphur compounds, it was found that it was not necessary to remove the sulphur compounds by chemical treatment before using the bauxite for decolorising (though this procedure may still be preferable in certain circumstances on considerations of cost), and that an appropriate bauxite treatment would effect the double purpose.

In June 1918 the first series of successful experi- ments on desulphurising kerosene and benzine by means of bauxite was recorded.

The bauxite was first heated to dull red heat in an oven and used at 200°. This reduced the sulphur in kerosene from 0·134% to less than 0·02%. It was found, moreover, that under the same conditions, but allowing the bauxite to cool in the open air before use, the resulting sulphur was 0·11%. In the light of recent research the first result was due, not to the temperature at which the bauxite was used, but to the absence of moisture from the pores. The proportion of bauxite to kerosene was varied in a series of experiments from 2 to 9 lb. per gallon with the results shown in Table I.

It is interesting to note that in this investigation, mention is made of the rise in temperature which ensues when the kerosene comes in contact with the adsorbent material. This temperature rise became, eventually, the fundamental principle of the "ergo- meter," an apparatus by means of which the efficiency of bauxite is tested.

The following conclusions were arrived at from these experiments:—

* Read at a meeting of the London Section on May 5, 1924.

(1) Bauxite is a colloidal adsorbent of the first order for organic sulphur derivatives.
(2) Freshness of preparation gives best results—*i.e.*, ignition immediately before use.
(3) Bauxite *per se* is a complete and sufficient refining agent for kerosene.
(4) Other sulphurous distillates are also capable of purification by this process.

It was found that the adsorbed sulphur compounds could be to a large extent removed from the exhausted bauxite by means of superheated steam, and to a lesser extent by hot water.

TABLE I.

Material	Treatment.	Sulphur. %
Kerosene	None	0·131
,,	9 lb. bauxite hot from oven, temperature approx 200°* ..	0·017
,,	4 lb. bauxite hot from oven (200°)*	0·017
,,	9 lb. bauxite not freshly ignited	0·110

* Minimum time from oven to treatment

The size of mesh which the bauxite would pass was found to have considerable bearing on the efficiency of the desulphurisation. Very broadly, the smaller the size of particle the greater the efficiency for removing colour, but the slower the rate of filtration; whilst for desulphurisation it was found that 30/60 mesh was the optimum size for small scale working, 20/90 mesh has to be used on the works scale to save waste and to ensure that the oil is in contact with the bauxite for a sufficient length of time.

At this stage refinery opinion on the bauxite process was that it was an excellent decolorising and desulphurising agent, but inconsistent in results. This was afterwards proved to be due to inefficient roasting. Distilling the oil through bauxite was found efficient but inconvenient, whilst filtration through bauxite dust was too lengthy an operation as well as inefficient as regards sulphur removal, though good for decolorising. By agitating oil and dust together, some excellent kerosenes were prepared, but simple filtration through bauxite of 30/60 mesh has proved to be the most convenient method of working the process.

In spite of the fact that bauxite has been used for many years in the refining of petroleum, the mechanism of the reactions which takes place has only been explained recently. It is now practically certain that the phenomenon is one of surface adsorption, and the action of bauxite upon sulphurous oils appears to be strictly analogous with known cases of true adsorption.

(1) Material such as roasted bauxite containing large numbers of microscopic pores is well known to possess an enormous surface area and consequent surface energy.
(2) When oil is allowed to come into contact with freshly-ignited bauxite a considerable rise in temperature is observed, due to the su energy being converted into heat energy
(3) Bauxite obeys Freundlich's rule, which m summarised as follows: $(x/m)^n$ is propor to c, where (in this case) $x = \%$ of to adsorbed by bauxite, $m =$ wt. of bauxit 100 parts kerosene, $c = \%$ of sulphur in sene before filtration, $n =$ a constant.

This formula has been deduced from, and prov apply in, many cases which cannot possibly be than true adsorption—cases in which any che action is out of the question. This being so, reasonable to suppose that the action of bauxi sulphurous kerosene is also true adsorption, the same fundamental law holds in each case.

Experimental verification of the Freundlich la applied to the adsorption of sulphur and colour pounds from kerosene by bauxite.

As a starting point, residue from soda-wa naphtha was used (sulphur, 0·3%; colour in Lovibond cell, Y 8·4, R 2·5). Samples (150 of a wide range of sulphur and colour concentra were prepared by treatment with quantities of ba varying between ¼ to 10 lb. per gallon. As colours to be measured extended far beyond range of the usual tintometers, a column of the lic of which the colour had to be measured, was mat against an equal column of the original crude k sene diluted with benzine, in the Saybolt colorim The colour concentrations so measured were expre as percentages of crude kerosene (thus the colo the original kerosene = 100).

A. Colour.—Six of the above samples with col ranging between 100% and 1·7% were treated ½ lb. of bauxite per gallon. The bauxite (2 mesh) was roasted 1 hour at 500°–540°, and co in a desiccator. 70 c.c. of each sample of kero were shaken for 10 minutes with 3·5 g. of bauxit 20°–21° in the mechanical shaker (5% by wei or ½ lb. per gal.):—

TABLE II.

Initial colour.	Final colour	% Colour removed	x/m
100	52	48	9·6
58	32	45	5·2
42	21	50	4·2
14·2	5·5	61	1·[illegible]
4·6	2·2	52	0·45
3·5	1·7	62	0·34
1·7	0·8	53	0·17

The values of x/m (amount of colour adsorbed gram of bauxite), plotted against the initial co concentrations, give approximately a straight Hence, for coloured compounds, x/m is proportiona the initial concentration of the colour, and Freundlich law is followed approximately, constant $n =$ 1.

B. Sulphur.—Six of the above samples hav sulphur concentrations ranging between 0·23% 0·017% and colours from 3·5% to 0 were trea with 2 lb. of bauxite per gallon. The bauxite prepared in same manner as before. 70 c.c. of e sample were shaken as before, with 14 g. of baux *i.e.*, 2 lb. per gallon. (See Table III.)

In this case x/m = grams of sulphur adsorbed gram of bauxite. These values, when plotted aga

initial sulphur concentration, give a graph ìich more or less approximates to a straight line. the logarithms of the quantities are plotted, a rve is obtained which approximates more closely a straight line. Hence we conclude that for lphur compounds the adsorption only approxi- ıtely follows the Freundlich law. The mean ıdient of the log curve indicates that the value n is of the order of 1·3, *i.e.*, $(x/m)^{1\cdot 3} = k.c.$

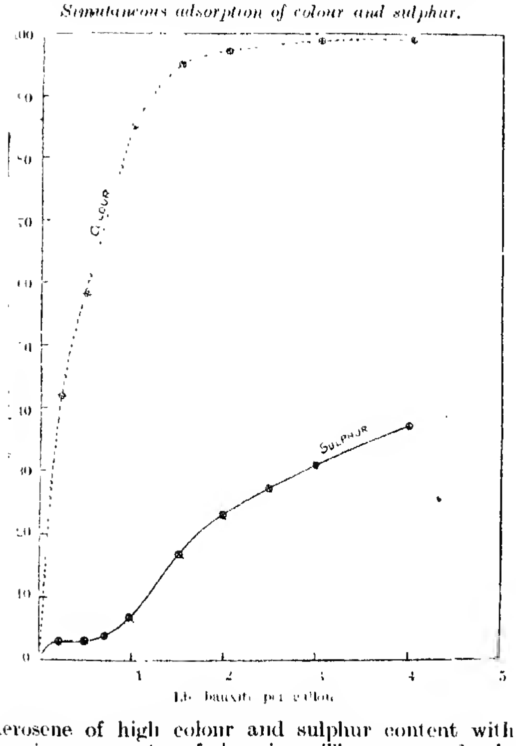
TABLE. III.

al S.	Initial colour.	Final % S.	% S re- moved.	$\frac{x}{m}\times 100$.	$\text{Log}\frac{x}{m}\times 100$	Initial S (g.)	Log Initial S (g.)
0	1·9	0·232	19·7	0·222	$\bar{1}$·3463	0·158	$\bar{1}$·1987
30	3·5	0·20	13	0·117	$\bar{1}$·0682	0·128	$\bar{1}$·1004
07	1·4	0·168	18·9	0·152	$\bar{1}$·1818	0·113	$\bar{1}$·0719
26	0·6	0·103	18·3	0·090	$\bar{2}$·9542	0·069	$\bar{2}$·8388
96	0·2	0·074	23	0·086	$\bar{2}$·9345	0·052	$\bar{2}$·7160
27	—	0·017	37	0·039	$\bar{2}$·5911	0·015	$\bar{2}$·176.

The deviation is no doubt due to the disturbing luence of coloured compounds which are prefer- tially adsorbed.

With regard to the question as to whether the eundlich law holds good for the simultaneous sorption of both colour and sulphur compounds, e results are best understood by reference to the companying figure. This was obtained by treating

Simultaneous adsorption of colour and sulphur.



kerosene of high colour and sulphur content with varying amounts of bauxite. The curve clearly shows that the coloured compounds are adsorbed much more rapidly than, and in preference to, the sulphur compounds. Thus until 85% of the colour has been removed only a small fraction of the sulphur is taken up, but once most of the colour is adsorbed then the removal of sulphur follows the usual course.

The point representing colour 3·5 (Table III.) lies considerably below the line x/m sulphur. The comparatively high colour concentration has lowered the adsorption of sulphur. This bears out the theory of preferential adsorption of colour.

Bauxite as a polymerising agent.

Like all substances possessing a structure consisting of ultramicroscopic capillary tubes, bauxite has the power to bring about chemical changes in compounds with which it comes in contact. This is mostly in evidence among unsaturated hydrocarbon compounds (*e.g.*, pinene and amylene are converted into dipolymerides), and is also seen in the case of the sulphur compounds present in petroleum oils. Decomposition and polymerisation both take place, the intensity of the reactions being favoured by increase of temperature.

If cracked spirit, which contains a large proportion of unsaturated hydrocarbons, is filtered cold through bauxite, the filtrate will be a deeper colour than the original, and if colourless beforehand the spirit will issue from the filter with a deep yellow colour. By maintaining the bauxite at about 100° an orange-brown filtrate is obtained, but if the temperature is raised above the final boiling point of the spirit, say 200°, the issuing vapour on condensing will be perfectly colourless and substantially free from sulphur compounds. The explanation of these results is as follows:—Polymerisation of unsaturated compounds takes place in contact with the bauxite to gums of high molecular weight and boiling point and possessing a dark colour. In the cases of filtration cold and at 100° the incoming liquid dissolves these gums and washes them out of the bauxite, but in the vapour filtration the gums remain in the filtering material because their boiling point is above the surrounding temperature. A similar reaction takes place in the case of the sulphur compounds, the majority of which are very reactive and readily undergo polymerisation.

Two methods of refining petrol or cracked spirit are therefore available: (*a*) by passing the liquid into bauxite maintained at a temperature of about 200°, when it instantly vaporises and passes through the filtering medium in the state of vapour, and (*b*) by passing the liquid through bauxite maintained at 100° and re-distilling the filtrate in the ordinary way. In process (*a*) the gumming polymers remain behind in the bauxite and gradually contaminate it, but a finished product is obtained in one operation. In process (*b*) the polymers are washed out of the bauxite, and thus the active life of the latter is maintained for a longer period. In the subsequent distillation the polymers, being of high boiling point, remain behind in the still, and a colourless distillate is obtained which is free from those compounds which form gum in cracked spirit on standing. The sulphur compounds in petrol are removed in the same way as the gum-forming compounds in cracked spirit. Sulphur compounds in kerosene can also be removed by an adaptation of process (*b*), wherein kerosene is

filtered through bauxite at a temperature of 100°—130° and then cooled and filtered through bauxite at the ordinary temperature. By polymerising the sulphur compounds in the hot filter they are rendered more easily removable by the cold filter than would have been the case if the hot filter were replaced by a cold one. A crude kerosene with a sulphur content of 0·31% was filtered through bauxite maintained at 120° at the rate of 1 lb. per gallon, and the filtrate then re-filtered through cold bauxite at the same rate. After the passage through hot bauxite the sulphur content was 0·26%, and after the subsequent cold filtration it fell to 0·16%. Ordinary filtration through 2 lb. of cold bauxite gave a filtrate with a sulphur content of 0·21%.

The present method of using bauxite may be divided into the following stages:

(1) *Filtration.*—A predetermined volume of oil is filtered through a definite weight of bauxite.

(2) *Steaming out.*—The filter is steamed out until no further kerosene can be removed economically.

(3) *Make up.*—Fresh bauxite is ground to size, and the required quantity added to make up for losses in working.

(4) *Roasting.*—The fresh make-up bauxite and the spent material are roasted in excess of air to remove moisture, the last traces of kerosene, and firmly retained organic matter and carbon, thus freeing the pores for a new run.

In order to understand the conditions required for successful filtration, it is necessary to consider the coloured compounds and sulphur compounds contained in the oil, which may be divided roughly into two groups:—

(1) Those in true solution (sulphur derivatives);

(2) Those in colloidal suspension (colouring matter).

Solid matter in coarse suspension can be removed by purely mechanical filtration through non-adsorbent material such as sand, but matter in solution or colloidal suspension can only be taken out by true adsorption into the pores of some active material of the nature of bauxite. The top layers of the bauxite are therefore engaged in removing the suspended coloured compounds, which cover over the pores and prevent the matter in solution from being adsorbed until it reaches a lower stratum, at which point all the suspended material has been left behind. As soon as these coloured compounds have been removed the bauxite is ready to deal with the sulphur compounds, which are hardly touched at all until the major part of the colour has already gone.

Taking, then, the successive layers of bauxite in a filter, the top is occupied in mechanically removing suspended matter, the next layer takes out the rest of the colour, and the lower layers eliminate the sulphur compounds. In this way, the three active zones move downwards until the coloured compounds are being extracted at the very bottom of the filter. But as no sulphur is taken out until almost all colour has gone, it will be seen that at this stage no sulphur is being eliminated at all. In other words the bauxite is exhausted for desulphurising purposes; it is still capable, however, of removing colour.

For this reason "series-filtration" gives the efficient and economical results. The principle u: lying series-filtration is that of putting the va layers of a large filter into a number of sm filters, so that each layer is capable of rejectic soon as it is exhausted, while no layer is rejected completely exhausted both for decolorising desulphurising.

In working the series-filtration much light thrown on the elimination of colour and sul compounds, for it was found that it was only the filtrate came in contact with fresh bauxite in last filter that any substantial desulphurisation place. Colour was progressively removed in pas through the series of filters, but sulphur compo were only removed in the last filter, as is shown ir following table:—

TABLE IV.

Filter.	Colour of filtrate (Saybolt).	% S in filtrate.	% of tot removed by
1	16°	0 286	8
2	17°	0 286	0
3	18°	0 286	0
4	19°	0 252	19
5 (fresh bauxite)	22°	0 129	60

The principle of first removing colour in orde allow the bauxite full scope to use its desulphuri properties, was employed by placing a layer floridin above the bauxite in the filter. Floridin better decolorising but poorer desulphurising ag than bauxite, and thus each material is made perform that operation for which it is best sui Better results were thus obtained than by using ei material separately. In the following experiment filters were run until the issuing kerosene gav positive reaction with sodium plumbite:—

TABLE V.

Bauxite. g	Filtrate c c	Bauxite and floridin. g g	Filtrate. c c.	Increas %.
10	75	10 + 0	75	—
11	82	10 + 1	90	+ 9
12	90	10 + 2	110	+22
13	97	10 + 3	120	+24
14	105	10 + 4	130	+24
20	150	10 +10	120	−20

The "increase" is the entire amount filtera before a positive reaction occurs with sodium plui ite, by replacing certain amounts of bauxite by eq weights of floridin. Practically no advantage gained by replacing more than 20% of the baux by floridin, and at some point between 30 and 50% diminution in efficiency commences to take place

With 17% floridin and 83% bauxite, the follow figures were obtained:—

TABLE VI.

	Bauxite.	Bauxite and floridin
At 6 lb per gall.	S = 0 122%	S = 0 09%
,, 3 lb ,,	S = 0 163%	S 0 14%
	Original S 0 265%	

By mixing the bauxite and floridin intimate together no advantage is obtained over bauxite alo since a portion of the latter is then occupied in : moving colour instead of being free to adsorb sulph compounds.

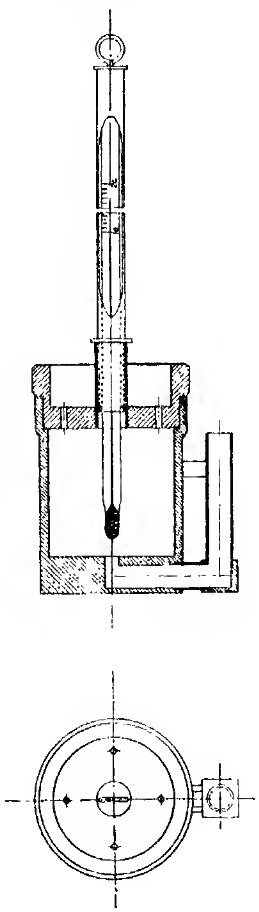
The failure of a filter occasionally to give a go product was attributed to the fact that a long peri of time had elapsed between the initial distillati

the filtration, *i.e.*, to the age of the kerosene. s, however, appears to be fallacious, as the follow- results show, the reason for the improved results bably being that agglomeration of coloured com- unds takes place which renders them easier of ention by the bauxite :—

TABLE VII.

Time after distillation. Days.	% Sulphur in filtrate.	Colour of filtrate (Saybolt).
—	0·116	14°
5	0·11	15°
10	0·086	16
21	0·083	19°
31	0·102	21°

One of the factors which determine the efficiency the bauxite process is the grade of bauxite. A igh-grade bauxite has a large proportion of pore pace, this being directly proportional to the efficiency



Ergometer.
(Half scale)

f the other conditions remain the same. The other esirable characteristic is hardness without brittleness. This is purely an economic desideratum, because a soft or brittle bauxite crumbles badly in the grinding and roasting and the dust formed is waste.

It must be emphasised at this point that it is impossible to find by chemical analysis whether a bauxite is high or low grade, as this appears to have no connexion whatever with its efficiency. Although the proportion of moisture in new unused bauxite is found to be roughly a measure of the pore space, this does not apply to used bauxite. In consequence, the method of testing new or recently activated bauxite for efficiency was a long and laborious task, involving actual filtration tests for colour and sulphur removal.

The length of time required for these tests prohibited their use except for consignments of new bauxite. It was impossible to test samples taken during the roasting of old bauxite to see whether it had received enough treatment or not, so the roasting was carried out empirically in the hope that it would "turn out all right."

It had been observed, however, that when kerosene is allowed to come into contact with activated baux- ite, a considerable rise of temperature occurs, and it was found that the greater the rise, the more efficient is the bauxite for removing colour, while the desul- phurising power is directly proportional to the rise in temperature. This fact has been made use of in practice to determine when the bauxite has been sufficiently roasted, the test being carried out as follows in an apparatus named an "ergometer," illustrated in the accompanying diagram

Sixty grams of freshly-roasted bauxite are cooled to the same temperature as the kerosene residue which is to be used in the test. The bauxite is then placed in the ergometer, which is a metal cylinder 1½ in. in height and 1½ in. in diameter, and holds about 50 grams 20/90 mesh, the temperature being observed by means of a thermometer fitted into a hole in the lid. 20 c.c. of the kerosene are poured into the cup-lid and flow through four small holes on to the bauxite, this quantity being just sufficient to wet the bauxite. The temperature soon com- mences to mount and the maximum rise is taken as the "ergometer number." A new bauxite of good quality which has been properly roasted will give a rise of about 16°. Regenerated bauxite should give 12°–14° rise; and if the rise is less than 10° faulty roasting is at once suspected. This temperature rise is reduced by a large percentage of fines. The total amount of time required for the test is about 10 minutes, so it is a rapid and convenient method of checking the efficacy of the roasting. Since the porous structure is created by the expulsion of water of hydration in the initial roasting, an alternative test for efficiency is available. It has been found that the activity of bauxite as a remover of sul- phur compounds from kerosene is directly propor- tional both to the temperature rise, as measured in the ergometer, and to the percentage of moisture that can be driven off by roasting at 400°–450°. With fresh bauxite therefore both of these phenomena can be used as a measure of activity, whilst in used bauxite the ergometer is the only test.

The following table shows that the maximum activity of various fresh bauxites obtained from

many different sources occurs when the material is roasted at 400° :—

TABLE VIII.

Temp of roasting.	Bauxite. I.	II	III.	IV.	V.	VI
0°	–	0 7°	—	1 1°	0·8°	0 8°
300	—	12 6	—	10 3	5·8	—
400	**18 8°**	**18 7**	**14 6°**	**12 8**	**9 3**	**8 1**
500	15 4	15 3	13 3	11 4	8 6	—
600	14 7	13 7	12 8	10 9	7 7	7 6
700	13	11 2		10 7	7 7	—
800	--	--	--	—	6 2	--
900	8 2	8 8	--	6 7	—	3 6

The following table shows the percentage of moisture removable by roasting at 400°, the ergometer rise (maximum) and the amount of total sulphur removed, all expressed in proportion with the worst sample of bauxite as unity. Direct proportionality—within experimental error– is seen to exist between these three sets of observations.

TABLE IX

Bauxite.	Water removed at 400° C	Ergometer rise.	Sulphur removed.	Colour of filtrate (Saybolt).
A	1	1°	1	18°
B	1 1	1 3	1	18 5
C	1 4	1 4	1 5	19
D	1 9	2	2	24
E	2 94	3	3	24
F	2 9	3 3	3	24
G	4 35	4 6	4	25
H	4 42	4 8	5	26
I	4 72	5 5	5	25

The colour of the filtrate improves progressively with the activity of the bauxite, but the exact relationship between the two has not yet been ascertained.

It is a well-known fact that to obtain the maximum efficiency from bauxite it should be cooled, after roasting, out of contact with air, and used as soon as possible. The reason for this is well shown by ergometer readings on samples exposed to the air for different periods, the decrease in efficiency, owing to adsorption of moisture, being clearly seen. Bauxite was roasted at 450° and divided into five parts :—

TABLE X.

(4) ,, ,, ,, ,, 6 hours	8 0
(5) Roasted and kept for 2 years in corked bottle	1 1
(6) No. 5 re-roasted at 400°	12 8

Influence of liquids other than kerosene on the ergometer reading.

With a view to ascertain whether the ergometer could be employed to detect impurities in oil and thus be used as a means of finding out if kerosene had been properly refined, a variety of different fractions and mixtures were tested with a given grade of bauxite roasted under similar conditions. The test proved, however, that the instrument was not sensitive enough for such fine distinctions, though in the widely differing fractions such as petroleum ether and liquid paraffin (medicinal) and liquids such as benzol and xylol pronounced differences in readings were obtained from those observed with kerosene and petrol.

From the above results it can be seen that it is impossible to detect benzol in aviation spirit (Nos. 6 and 7)—although benzol alone gives a distinctly higher reading than straight petrol—and therefore small amounts of impurities in kerosene could h[...] be expected to make a noticeable difference i[...] reading. When testing the activity of bauxit[...] means of the ergometer, it therefore makes lit[...]

The mesh of the bauxite has a considerable [...] on its efficiency. For colour removal, the fi[...] mesh the better are the results—probably o[...] the longer time of contact. For sulphur r[...] efficiency increases with fineness of mesh to a[...]mum, after which increased fineness causes a d[...] in efficiency. The optimum mesh was foun[...] 30/60. This is not practicable on a works[...] because all bauxite finer than 60-mesh would [...] be rejected; thus much greater latitude is e[...] and 20/90-mesh is used. This latitude has adv[...] other than economic. One of the dangers wit[...] the refiner is faced when packing his filters wit[...] mesh bauxite is the formation of channels

ckets. These form a line of least resistance for the , which promptly follows the channels, with the ult that the kerosene merely washes the outside the coarse granules instead of percolating unirmly through the mass. This causes an immense s of efficiency, which is counteracted by the use a wider range of mesh, for then the small particles up the spaces between the larger ones and so tend eliminate channels and air pockets.

The shape and size of the filter does not appear be a vital factor. A convenient size to handle is e of 1 to 2 tons capacity, although there is no reason limit the capacity to this figure. So long as the igth is sufficient to ensure that the oil is in ntact with the bauxite for not less than 15 to 20 inutes, the shape is unimportant and is influenced ly by convenience in handling.

Shape of filters and rate of filtration.

In order to see if any advantage accrued from igthening a filter, equal weights of bauxite were it in filters having a ratio of length to diameter of :1, 4:1, 8:1, 50:1, and an equal volume of rosene was passed through at similar rates.

TABLE XIII.

Ratio l d.	Colour of filtrate (Saybolt).	% Sulphur in filtrate.
2 1	24°	0 206
4 1	24 5°	0 210
8 1	25°	0 205
50 1	25°	0 193

From this it is evident that the shape of the filter within reason) is of no importance, provided that he liquid is in contact with the bauxite for a suffiient time, on which of course depends the pernissible rate of filtration. Three equal filters were un at rates in the proportion of 1 : 10 : 50.

TABLE XIV.

Rate	Colour of filtrate (Saybolt).	% Sulphur in filtrate.
1	24 5°	0 18
10	25°	0 18
50	20 5°	0 18

These figures show that elimination of sulphur compounds is more rapid than the removal of colour, and that it is possible to surpass the critical speed or colour before sulphur removal is effected.

Filtration efficiency is influenced to some extent by the temperature of the bauxite, and the material should be allowed to cool sufficiently to avoid vaporisation or overheating of the kerosene, but not enough to allow the adsorption of moisture. The most appropriate temperature is about 120°.

The elimination of sulphur compounds is not directly proportional to the amount of bauxite used, the curve rising steeply at first but flattening out fairly rapidly.

After the bauxite is exhausted it is allowed to drain for about 1 hour and is then steamed out. Shortly after steam begins to issue from the bottom of the filter the extraction is stopped, and bauxite thus treated with superheated steam (150°) comes out dry to the touch, though still containing 7—12% of moisture and kerosene. Further steaming removes but little kerosene in proportion to the amount of steam used.

The bauxite is next roasted to remove moisture and burn out adsorbed impurities that are not removed by steam. This necessitates a temperature of about 550° in the presence of ample air.

Furnacing.

Any furnace to be successful must fulfil the following desiderata :—(1) Too much grinding and crushing should not take place. (2) Whilst maintaining the temperature required, ample air must be present so that sufficient oxidation may take place. (3) The roasting temperature of 550° must be maintained for a sufficiently long time.

A great number of experiments have been made on treating the bauxite after use by solvents or solutions of chemicals before roasting, but no results were ever obtained which were an improvement on the simple process of steaming out the adherent kerosene. The solvents tried include petrol, alcohol, acetone, benzol, ether, carbon tetrachloride, and mixtures of these, whilst the chemical washes were sodium carbonate, caustic soda, soap, hydrochloric acid, ammonium phosphate, and water and steam under high pressure. In no case, however, was it possible by the use of either hot or cold treatment to remove the whole of the contained impurities, which could only be completely eliminated by roasting in a good oxidising atmosphere. After draining a filter, 90% of the remaining adherent kerosene can be removed by steam, the major portion being expelled before steam issues from the bottom of the filter, and by using steam at 150°–180° the bauxite is left dry to the touch and easy to handle. Another advantage in the steaming process lies in the fact that expulsion of the evil-smelling sulphur compounds does not commence until most of the kerosene is already displaced, whereby it is possible to recover a large portion of the retained kerosene in a fit state for re-filtering.

Various theories have been put forward to account for the supposed "poisoning" of bauxite after prolonged use, such as the formation of sulphates or chlorides of aluminium or iron by the sulphur and chlorine compounds in the oil. Analyses, however, have proved that no accumulation of either sulphate or chloride takes place provided efficient roasting has been employed. The same sample of bauxite has been used and recovered over and over again with very little loss in efficiency and practically no change in chemical composition. Formation of dust due to repeated roasting and cooling brings about a slow, progressive, slight decrease in efficiency, but an occasional sieving will prevent this and maintain a regular standard of activity.

The following tables give examples of regeneration experiments carried out by steaming at 120° and roasting at 600°.

TABLE XV.

20	23 5	51	9 4

The increase in dust in the bauxite concurrently with a slight falling off in desulphurising efficiency and lowering of the ergometer reading is clearly shown. The bauxite was steamed *in situ* in the filter and roasted in an externally heated rotary furnace at about 550°, thus being well exposed to a good supply of air, which constitutes the principal feature of successful roasting.

The use of the ergometer in ascertaining the correct conditions for properly roasting used bauxite is clearly seen in the following table :—

TABLE XIX.

	Material.	Roasting Temperature	Roasting Time	Ergometer reading.
		°	hr.	°
	New bauxite	500	1	15 4

(4)	" "	600	1¼	13 0
(5)	" "	600	3	14 6
(6)	" "	600	2½	15 1

In experiments 1—5 the bauxite was roasted in a dish in a muffle furnace in which there was not much circulation of air, but in experiment 6 a vc iron tube, heated externally, was employed in heated air was drawn through the mass o bauxite. The increased ergometer reading ind the extra efficiency obtained by thorough oxid of the material roasted. The deleterious e of chemical treatment as a means of assisti regenerating bauxite are also indicated by ergometer readings.

The temperature at which fresh bauxite is roa has a very distinct bearing on its efficiency, as a decolorising and a desulphurising agent, in order to obtain the best results it is absol necessary that great care be taken to maintain temperature of the furnace at the proper degree The following table shows this point very tinctly :—

TABLE XXI.

Temp of roasting.	Ergometer rise.	% Moisture remaining.	Colour of filtrate (Saybolt).	% S removed.	Effect of 9 n sunlight on fi

The highest temperature attainable in the furn used was 900°, and this was taken as giving c pletely anhydrous bauxite. Other workers, howe employing temperatures of 1500°, as in the cera industry, have observed that bauxite shrinks about half its original volume and in this stat quite valueless as a filtering agent. This due to collapse of the capillary pores owing to par fusion of the bauxite, and it can be seen in the ab table that this phenomenon commences betw 700° and 800°. For all-round efficiency fr bauxite should be roasted at about 400°, at wh the maximum ergometer rise is obtained.

It is also to be noted that the filtrate from bau roasted at 400°—*i.e.*, where maximum ergome rise is obtained—withstood the effects of light a air better than any of the others, which is additio proof that the maximum ergometer figure is a t indication of the state of greatest efficiency of baux

The result of a study of the use of bauxite dust a filtering agent lends additional strength to the the that the principal action of adsorption takes pl

in the capillary pores in the interior of the grains not on the surface of the latter. This applies fly to the sulphur compounds, which are in solution, but in the case of colour where a large portion is probably in colloidal suspension, action of filtration appears to take place largely he surface of the grains. The proof of this is in the increased colour-removing power with ease in size of the grains, whereby the total rnal surface area of a given weight of material ressively increases. Experimental evidence of is shown in the following table :—

TABLE XXII.

ih of auxite.	% of total S removed. By agitation.	% of total S removed. By percolation.	Colour of filtrate (Saybolt). By agitation. °	Colour of filtrate (Saybolt). By percolation. °
0	25	—		—

0	30	32	21	23
80	25	—	—	—
	24	—	22	—
ing 180	24	—	22¼	—

The maximum figure for removal of sulphur npounds occurring with 30-60 mesh bauxite is bably due to the diameter of the grains being he right order to give the most efficient length he capillary pores. Larger grains will contain s in the interior which have no opening to allow ance of the liquid, whilst in the smaller grains the s may be of a less efficient length.

he table also shows the superiority of the percolation method over that of agitation.

n making tests with the ergometer the effect of t and over-large particles must be taken into ount for two reasons : (a) the lower efficiency of se two extreme grades, and (b) the different ounts of liquid that can be held up by bauxite different mesh. Both these factors act in the same ection, *i.e.*, a lower ergometer reading, and consently bauxite that has been in use for some time l disintegrated to finer mesh by roasting and tion will show a slightly lower reading than the ginal, although it may be perfectly clean. The ct of mesh on the ergometer reading is shown in following table :—

TABLE XXIII.

Filtration under pressure and in vacuo.

In order to see whether it was possible to produce tter desulphurising by forcing the kerosene into pores of the bauxite, experiments were carried t in two directions : (a) in which pressures varying om 100 to 240 lb. per sq. in. were applied to the uid above the bauxite, and (b) by evacuating the ntainer in which the bauxite was placed to empty the pores of air and thus allow easier entrance of the kerosene.

The pressure experiments were first conducted in a Mahler bomb, the bauxite and kerosene being introduced together and pressure applied by means of a nitrogen cylinder. No appreciable result, however, was obtained.

TABLE XXIV.

Pressure.	% S in filtrate.
None	0 05
140 lb. per sq in.	0 04
240 ,, ,, ,, ,,	0 04

In the next experiments a U-tube filled with kerosene was attached by one limb to a steam boiler working under 100 lb. pressure, and by the other to the filter containing bauxite. In this way direct filtration was obtained under 100 lb. pressure, the rate of filtration being regulated by a valve at the bottom of the filter. Direct comparisons were then made by using the same filter under atmospheric pressure in the ordinary way.

TABLE XXV.

	100 lb pressure.	Atmospheric pressure.
S in filtrate	0 15%	0 13%
Colour of filtrate	22° Saybolt	23°
S in filtrate	0 22%	0 19%
Colour of filtrate	22° Saybolt	23°

It is evident from these results that increased pressure is of no assistance.

In the vacuum experiment the bauxite was first roasted in air to remove moisture, then transferred to a silica tube attached to a vacuum pump and heating continued for 15 minutes under a pressure of 2—3 mm. The bauxite was then cooled while still *in vacuo*, and kerosene introduced through a tap-funnel without allowing air to enter the tube. After standing for 5 minutes the vacuum was released in order to force kerosene into the pores of the bauxite, and 15 minutes later the kerosene was filtered off under suction. The experiment was repeated using the same apparatus, but without vacuum, for comparison with ordinary filtration.

TABLE XXVI.

	Vacuum. %	Atmospheric pressure. %
Sulphur in filtrate	0 077	0 137
	0 07	0·135

The experiment was next conducted on a larger scale, but in this case the bauxite was roasted in open air and immediately transferred hot to an iron filter in which it was allowed to cool *in vacuo*, the roasting *in vacuo* being dispensed with. The kerosene was run in, and after releasing the vacuum, filtration was performed in the ordinary way.

TABLE XXVII.

	Vacuum. %	Atmospheric. %
Sulphur in 1st 50 c c. of filtrate	0 049	0 04
,, ,, 2nd ,, ,, ,,	0 067	0 077
,, ,, 3rd & 4th ,, ,,	0 132	0 14
Average of whole	0 095	0 099

It appears from this that actual roasting *in vacuo* is necessary in order to free the pores of air, and unless this is done no advantage results, either because the pores have never been really evacuated, or they absorb air extremely rapidly during the short time between removal from the furnace and applica-

tion of the vacuum. Of the two possibilities the former appears probable. It had been hoped that cooling *in vacuo* might have effected an increase in activity, but as roasting *in vacuo* is the deciding factor, this puts the method out of court as regards practical importance.

The increase in activity by roasting *in vacuo* was also apparent from the large amount of heat evolved when the kerosene was run on to the bauxite. The silica tube felt to the touch about 40°, whereas in the comparison experiment without vacuum hardly any increase in temperature could be felt, although from ergometer readings it was known that a rise of about 16° must have taken place. A great difference was also noticeable between the bauxite from the two experiments after filtering off the kerosene, the material from the comparison experiment being of the usual red colour, whilst that from the vacuum treatment was black and had a strong odour of cracked kerosene, the odour of the two filtrates also differing in the same way. No such results were observed in the second series of experiments where actual roasting *in vacuo* was omitted. The increased activity described above must have been very pronounced if the blackening of the bauxite was due to formation of carbon, as the "cracked" odour appears to indicate, but this point was not actually confirmed. Attempts to measure the temperature rise when kerosene was added were unsuccessful, owing to the difficulty of constructing a suitable apparatus, but it is hoped to be able to carry this out later and extend the investigation.

THE TECHNICAL USE OF BAUXITE IN CONNEXION WITH PETROLEUM REFINING.*

BY A. M. O'BRIEN, F.I.C.

Bauxite as a refining agent was first introduced into the petroleum industry by The Burmah Oil Company as far back as 1908, and the author has been associated with its use on the practical scale from the initial days to the present time.

Bauxite, up to date, has been used principally in the granular form, being ground by suitable machinery with the minimum production of dust or "fines" (material that will pass through 90 meshes per square inch).

The best results obtained by the author to date have given not less than 20—25% of fines, calculated on the original bauxite fed to the grinder. There is a limit also to the maximum size of the granules, and this has usually been set at "everything passing through 10 meshes per square inch."

Before use the granules must be incinerated to remove moisture and combined water. This is usually achieved by roasting in excess of air in a rotary kiln, similar to a cement kiln, at 400°—600°.

* Read at a meeting of the London Section on May 5, 1924.

The minimum temperature at which bauxite c heated to obtain efficient results in the subse refining process, is about 350°.

As a test of efficient recovery, or roastin Research department of The Anglo-Persia Company has established a method know the "ergometer test," described in the pre paper. Whilst once roasted bauxite shows a l ergometer test than the same bauxite on subse re-roastings, yet, from a petroleum refining of view, the regenerated bauxite is as efficient once roasted material. If a bauxite after use regeneration exhibits a satisfactory ergometer *i.e.*, 10° rise or over, other things being equal, i reproduce the same results as when in the roasted condition.

The bauxite, after preparation, whether in initial or regeneration stages, should be co preferably without exposure to the atmos Using a water-cooled conveyor of the push plate the bauxite can be delivered at the necessary perature to the vessel intended for its use. temperature depends upon the purpose for whicl bauxite is to be used; *e.g.*, if desulphurising wit regard to colour is intended, then the bauxite probably be delivered into the receiving vess a much higher temperature than when reducti colour only is the objective.

The following results of a filtration of kere clearly indicate the relation of temperature to co and sulphur. The oil fed to the filter was yellow in a Lovibond 18-in. cell, and conta 0·17% of sulphur :—

Temperature of filtration.	Filtrate. Colour (18 in. cell) Lovibond. *Yell.* + *Red.*	Filtrate. Sulphur.
10°	1·5 + 0·40	0·091%
20	2·2 + 0·00	0·087%
30	2·9 + 0·10	0·085%
40	4·0 + 0·58	0·084%
50	6·0 + 0·7	0·08%
60	6·9 + 0·60	0·077%
70	7·4 + 0·5	0·075%
80	8·0 + 0·90	0·072%
90	9·6 + 0·70	0·068%
100	10·4 + 1·0	0·065%

The vessels in which the bauxite is used may v in size up to a 50,000-lb. or 100,000-lb. filter, yield comparable results, irrespective of capac

The container for the bauxite is usually a cylindr vessel, the dimensions of which are ascertained preliminary experiment. The bottom of the c tainer or filter usually carries a perforated grid, which is placed wire gauze, surmounted by fine li or blanket cloth, to hold the bauxite in positi From the underside of the grid it is advantage to take a small pipe up to above the level of the of the container, to prevent air locks by permitt the escape of air occluded in the bauxite and d placed downwards in the column by the incom filtrate. If this air-vent is not used, the bottom out of the filter should be opened as soon as the liq to be filtered is passed on to the top of the bauxi at the same time keeping the top of the baux

ays covered with oil until the total air has been placed from the column.

The most efficient control of the filtrate is by prior asurement of the oil to be filtered, and the comte passage of the whole of the measured quantity. precise method of working will eliminate many ubles by doing away with the personal factor.

After the charge has been filtered through, the er should be allowed to drain. This can be pedited by attaching a vacuum pump to the filter, th the insertion of a receiver between the filter and e pump. By this method the time required for aining of a 4000-lb. filter can be shortened from hours to 2½ hours, and a drier product obtained. ll more liquid may be removed by blowing steam to the bauxite. For example, in the case of rosene, on simple draining some 22% of the oil is tained by the bauxite; after the application of cuum this quantity will be reduced to 18%, or even wer, and with the application of steam to as low as –5%. Furthermore, the time can be reduced from hours by vacuum draining, to 1 hour by vacuum us steam.

Before regenerating the bauxite it is advisable to dd a certain amount of fresh bauxite to make up for e amount lost as "fines" during the handling and sting.

Since bauxite is self-abrasive, transport through a ugh and continuous screw is not desirable. If a veyor with a central shaft is used, it should have ddles set tangentially instead of a continuous m or screw. It is preferable to make use of gies as much as possible, elevation being obtained lifts as and when necessary, and not by bucket vators.

Although for ordinary purposes the optimum size granule is from 10 to 90 meshes per sq. in., a much er grade (almost impalpable powder) can be used h liquids of an extremely low viscosity and high rmeability, such as petrols.

A recent development in the preparation of bauxite s been established on the practical scale by the thor, in which the ground bauxite is charged into the ntainer, and there heated by means of superated steam to a temperature not lower than 350°, er which it is cooled by passing dried air through The liquid to be refined is then passed through e filter, the quantity having been previously termined. The bauxite charge is afterwards subcted to steam, aided by the vacuum pump, and hen fully drained is again treated with superheated eam at a temperature of 350° for regeneration as reviously stated. These operations are carried on ternately.

This method of re-activation precludes a great eal of waste as compared with the method previously described. Furthermore, it minimises the amount of labour required on the plant; in fact, maintenance and running charges are reduced to a minimum.

The use of superheated steam might appear extravagant, but in view of the increased life of the bauxite it is a very economical proposition.

THE DYEING PROPERTIES OF SOME SCOTTISH LICHENS, AND OF A FEW OTHER MATERIALS.

BY T. S. PATTERSON, D.SC., PH.D.

At the instance of the Board of Agriculture for Scotland, Mr. E. J. A. Stewart, M.A., B.Sc., recently collected samples of a number of lichens in various districts of Scotland, and these were handed to me for a comparison of their tinctorial properties. In the majority of tests 5 g. of the specimen were used, but in some instances, where less than 5 g. was available, smaller quantities had to be worked with. Again since many of the samples amounted to little or no more than 5 g., there was small opportunity for variety of treatment, and only one experiment could be carried out. This, of course, rendered it necessary to adopt a uniform procedure such as appeared to be of widest application.

In the dyeing tests, therefore, the following general process was adopted:- 5 g. of the specimen were placed in a 600 c.c. beaker with 250 c.c. of water and 50 c.c. of concentrated ammonia solution. A piece of flannel, six inches long by three broad and weighing approximately 2·5 g., previously wrung out of hot water, was added, and the temperature gradually raised to near the boiling point and kept there for some four hours, another 100 c.c. of water and 50 c.c. of concentrated ammonia being added after about half that time had elapsed. The solution at the end of the four hours had generally evaporated down as far as was possible without risking the breaking of the beaker, so that the dyeing was forced in each case as far as it would go. The flannel was then removed from the solution, washed thoroughly with warm water, and dried. It is not possible to give a satisfactory account of these experiments as a whole without samples of the dyed material, but since it may be useful to others, a few of the results obtained may briefly be mentioned.

Samples of *Parmelia physodes*, Ach., *P. saxatilis*, Ach., and *P. omphalodes*, Ach., were supplied, but as they are already well known and in actual use in various parts of Scotland as the "Crottles," it is not necessary to refer to them. They serve, however, as a standard by which to judge some of the other lichens.

The dyeing properties of *Usnea hirta*, Hoffm., have been described by A. Edge (J. Soc. Dyers and Colourists, 1915, **31**, 3), who found it to give, without ammonia, after short treatment, a yellow colour, and on longer treatment, an orange-brown colour. Dyed from an ammonia solution I found it to give a brownish colour of a yellowish-green shade of no use except perhaps as a standard by which to judge some of the other lichens. Thus, *Evernia prunastri*, Ach., gives a somewhat similar shade to *Usnea hirta*, with rather more colouring matter, but a slightly greater tendency to greenness. *Lobaria pulmonaria*, Hoffm., gave a brownish colour with a little less green in it, and *Sphaerophorus coralloides*, Pers., gave a somewhat better brown. *Platysma glaucum*, Nyl., gave also a greenish-brown shade, although when dyed from an acid bath it gave a

more satisfactory warm fawn colour which might possibly be useful.

Ramalina farinacea, Ach., *Parmelia conspersa f. isidiata*, Leight., both also gave brown shades, the latter evidently containing more colouring matter. *Lobarina scrobiculata*, Nyl., also gave a brown shade of no very great value, but *Lecanora ventosa*, Ach., gave a good deep purple-brown colour which might be of distinct value and is, perhaps, worth further investigation.

Pertusaria dealbata, Nyl, was one of the best lichens examined for the production of a warm brown shade, being distinctly superior to the "Crottles." This is, however, a hard and stony lichen, very difficult to collect from the boulders upon which it grows.

Physcia parietina, De Not, *Stereocaulon coralloides*, Fr., *Cetraria aculeata*, Fr, and *Sphaerophorus fragilis*, Ach., gave delicate grey shades, perhaps better greys being produced by *Parmelia fuliginosa*, Nyl, *Gyrophora cylindrica*, Ach., and *Gyrophora proboscidea*, Ach.; *Ramalina subfarinacea*, Nyl., gives a fairly satisfactory brown shade

Additional experiments were carried out with some of the lichens available in greater quantity. Thus 30 g of a sample of *Parmelia saxatilis* were extracted with boiling water. Flannel dyed with this extract gave a good warm orange-brown. The solution after addition of ammonia dyed a much deeper warm chocolate-brown colour. Similar results were secured from *Parmelia omphalodes*. Another sample of flannel was first mordanted with potassium bichromate and dyed with an ammoniacal extract from *Parmelia omphalodes*, but the addition of the mordant seemed to make little difference in the colour obtained

Various samples of *Lecanora tartarea*, Ach, were submitted. They gave satisfactory results; but as this lichen is already well known they need not be referred to except to state that a portion of a sample from the rocks of Craigellachie, Aviemore, where the lichen is reported by Mr. Stewart to be very abundant, was extracted with absolute alcohol in a Soxhlet apparatus and the alcoholic extract evaporated to dryness From 79 g. of lichen 15·2 g. of extract were obtained This extract dyed, with ammonia, a fine purple colour, which seemed to be of a slightly bluer shade than that obtained from the lichen directly. This might possibly be due to ethylation of the hydroxyl group of the orcinol molecule, ethylation being known to produce this effect in certain other cases

A few other substances were submitted for examination in regard to their tinctorial properties. Of those the best was probably the root of Rhu (*Galium verum*, Linn, Lady's Bedstraw); the colouring matter is contained in the thin outer cover of the root, and dyes a fairly satisfactory terra-cotta colour. With this root the results obtained from aqueous solution without ammonia appear to be better than in presence of ammonia.

In the samples of *Lecanora tartarea* the quantity of orcinol present in the lichen was determined, since it is upon this that the value of the substance depends for the preparation of orchil. Fc purpose two methods somewhat similar in pr have been suggested. One of these is that orig proposed by Stenhouse (Phil. Trans., 184 and improved by H. E. Watt (J., 1908, 61 weighed quantity of the lichen is maceratec sodium carbonate solution, excess of hypoc solution is then added, and the excess titratec with arsenious acid. From the quantity of chlorite used, the quantity of orcinol present m determined. The second method is essentiall of Reymann (Ber., 1875, 8, 790). About 2·5 the powdered lichen are placed in a flask, 25 c $N/1$ caustic soda solution added, the solution up to 250 c.c., and the contents of the flask shaken. When the mixture has settled, 50 of the solution are withdrawn. To this are 5 c.c. of a solution of a mixture made up of of sodium bromide and 25 g. of sodium broma one litre of water. Some hydrochloric acid then some potassium iodide solution are a Bromine, liberated from the mixture of so bromide and sodium bromate, attacks the orc By titrating the iodine liberated by the exce bromine from the potassium iodide, the or content of the lichen can be calculated.

It appears that neither of these methods is gether reliable since they are based on the assum that there is nothing else in the lichen likely t acted upon by the two reagents mentioned. following table, however, gives the results of analyses which were carried out:—

Orcinol content of Lecanora tartarea.

Origin of specimen	Percentage of orcinol. Stenhouse-Watt I	II.	Mean		Reymann I.	II.	I
1. Boulders, Glen Nevis	3·18	3·47	3·32	.	—	—	
2. Crags and moss, Stob Garbh, Ben Laoigh	3·84	4·00	3·92	..	4·69	4·38	
3. Rocks Craigellachie, Aviemore (locally very abundant)	3·6	3·7	3·65	..	–	—	
4. Rocks, Aviemore	3·22	3·16	3·19	.	4·87	4·04	
5. Birch trees, Aviemore	1·15	—	--	.	2·21	1·94	
6. Trees, Glen Garry	2·08	2·10	2·09	..	3·38	3·23	

It will be seen that the analyses by the Stenhou Watt method are consistently higher than th by the bromine method, and since it appears proba that the bromine method is likely to give h rather than low results, the data given by the brom method are probably the more correct.

I am indebted to the Board of Agriculture Scotland for kindly consenting to the publicati of this paper.

University of Glasgow.

THE INFLUENCE OF MICRO-ORGANISMS THE WEATHERING OF WOOL AND COTTON.

BY S. R. TROTMAN AND R. W. SUTTON.

In describing the properties of a textile fibr a high place is given to durability or permanen when exposed to air under ordinary condition Unless a fibre possesses this property to a marke

rce it is, naturally, of little use for textile pur-es. But no known fibre can be described as lly permanent, though cellulose acetate approaches s ideal very closely. Quite apart from the stresses d strains of ordinary wear, there is another factor ich causes the gradual disintegration of textile terials and which, for want of a better name, is med "weathering." Sensitiveness to the influence weathering is, thus, an important property, and ich work has been done with the object of deter-ning the causes which produce this effect. These

Langsdale (J., 1923, 12 T) showed that air containing small quantities of ozone attacked the epithelial scales, producing soluble sulphur and an increased percentage of soluble nitrogen. Oxidising agents such as persulphates produce a yellowish colour similar to that of weathered wool and cause rapid destruction of both epithelial scales and tensile strength. They proved also (*loc. cit.*) that effects similar to weathering could be produced by the action of bacteria such as *B. subtilis*. In fact it appears likely that bacteria play a considerable part

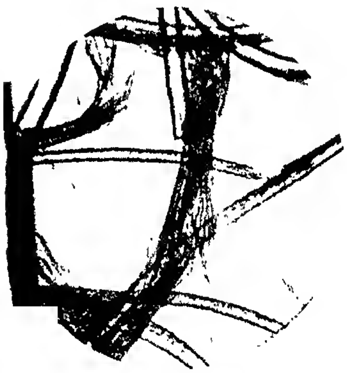

FIG. 2.

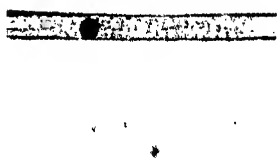

FIG. 1.

FIG. 3.

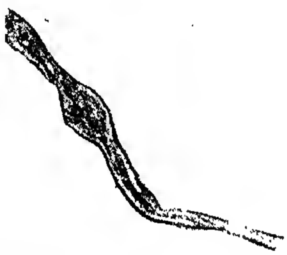

FIG. 4.

FIG. 5.

complex. The power of resistance to weathering y be diminished by faulty physical or chemical cesses in the preparation of the goods. Atmo-eric oxygen and actinic light appear to be among chief causes of natural weathering. Thus, in case of wool, Kertesz (J., 1919, 496A) concludes at all the effects of weathering could be produced y actinic light alone, and that while ozone produces nderness it does not give rise to the peculiar effects ssociated with weathering. Whitaker (J., 1914, 79) has suggested that weathering is accompanied by de-amination, whilst Fort and Lloyd (J., 1914, 306) arrived at an exactly contrary conclusion, namely, that free amino groups are produced. Trotman and

in the destruction of textile fibres by weathering. These experiments have now been confirmed.

Pieces of woollen fabric were sterilised by boiling with water, inoculated with a culture of *B. subtilis*, and incubated at 37·5°. The progressive damage can be followed easily by microscopical examination. At the end of 48 hours the epithelial scales had become faint in outline and in some cases had disappeared entirely. A fibre is shown in Fig. 1.

At this stage the fabric had a decreased shrinking power and an apparent increased affinity for acid dyestuffs. The shrinkage diminished in one case from 35·4% to 11·2%. Upon continued incubation, the fabric became gradually thinner and the scales

disappeared altogether. In about five days it was quite rotten and the fibres had become disintegrated with the liberation of the spindle-shaped cortical cells (Figs. 2 and 3).

The apparent affinity for both acid and basic dyestuffs was considerably greater than in the original material, but the fabric broke down altogether when boiled with water. The solution obtained contained sulphides, gave a precipitate with tannic acid, a strong biuret reaction, a turbidity with Acid Magenta and Methylene Blue, but no precipitate with ammonium sulphate. Similar results were obtained with *B. mesentericus*—another common aereal organism.

The action of B. subtilis on cotton.

The weathering of cotton has been investigated by Cross, Dorée, Turner, and others. Both Dorée and Turner arrived at the same conclusion, namely, that actinic rays were the chief disintegrating agent. Removal of the oxygen from the air surrounding the fibres reduced the destructive action of light but did not eliminate it entirely. The presence of small quantities of ozone accelerated the weathering effects. Dorée concluded that light has a twofold action on cotton. The ultraviolet rays exercise a physical disintegrating effect. If the cotton contains moisture, traces of ozone are also formed on the surface. Ozone attacks cellulose producing a cellulose peroxide, an acid derivative, and carbon dioxide. These effects are intensified by the presence of traces of metallic compounds which act as catalysts.

Micro-organisms constitute another factor in weathering, the importance of which is sometimes overlooked. Fleming and Thaysen (Biochem. J., 1920, 25; 1921, 407) found that good Indian raw cotton contained normally 1·4 million bacteria per gram. If less than 9% of moisture is present this number does not increase, but when the water content exceeds 9% growth is very rapid. They employed a swelling test, depending upon the presence of the cuticle to determine whether cotton hairs have been attacked by bacteria. When treated with a cellulose solvent such as Schweitzer solution, an undamaged hair shows the characteristic globular swellings, while if attacked by bacteria the cell walls swell up uniformly owing to the absence of cuticle.

When cotton is incubated with a culture of *B. subtilis* the first effect observed is a swelling up of the cell walls and loss of natural twist. This is accompanied by the formation of occasional globular swellings (Fig. 4) which sometimes cause rupture of the cuticle (Fig. 5). These swellings are not identical with those described by Denham (J. Textile Inst., 1923, T124), since they were not found in the original cotton. The tensile strength, in the case of cotton yarns, increased slightly at first, reaching a maximum in three days. After this it decreased, becoming less than that of the original cotton. The water content was in all cases the same when the samples were tested.

The following table illustrates the rise and fall in tensile strength:—

Time of incubation	Tensile strength.
Original cotton	15·0
After 24 hours	15·4
„ 48 „	16·5
„ 96 „	18·4
„ 7 days	12·0

The swelling is accompanied by a slight decrease in length. The tensile strength increases as the swelling proceeds, till the globular formations become marked. Loss of tensile strength seems to become apparent when the globular swellings are eviden[illegible] The incubated cotton appears also to have a sligh[illegible] increased affinity for Benzopurpurin. These poi[illegible] are summarised in the following table. Six lots [illegible] Egyptian cotton yarn, each exactly 60 yards [illegible] length, were inoculated with a culture of *B. sub*[illegible] and incubated at 37·5°. One lot was removed [illegible] the end of each three days, washed, and examined. At the end of the experiment the samples, togethe[r] with a control, were wetted with water and allowe[d] to dry at room temperature for several days to ensure the same "condition" with regard to moisture:—

No. exp.	Duration of exp. Days.	Length yd.	in.	Tensile strength	Micro[illegible] appearance
0	—	60	0	1·30	
1	4	60	0	1·34	Fibres sw[illegible] with little [illegible]
2	7	60	0	1·43	„
3	10	59	2	1·45	„
4	13	59	25	0·95	Increase in [illegible]age
5	16	59	25	0·97	„ „
6	19	59	2	1·00	„ „

Samples Nos. 4, 5, and 6 contained [m]ore of the globular swellings than the earlier on[es] and it will be noticed that this point corres[ponds] with the decrease in tensile strength. In all [case]s Schweitzer reagent gave very few charac[teri]stic globular swellings.

The use of *B. subtilis* has been [advocate]d for [the] removal of proteins from cotto[n]. The p[ercentage] of nitrogen present in the cotto[n was d]etermined [at] the beginning and end of the [experimen]t. Only [a] very small decrease was found [and this] has b[een] confirmed on other occasions, an[d it is] proba[ble] that *B. subtilis* is of little use for this [purp]ose. [Nor] does it remove starch nearly as rapidly as diast[ase], though the contrary has been maintai[ned] by ot[her] observers. The action of *B. mesenteri[cus]* [was] tes[ted] in a similar manner. As with wool, th[e] [res]ults w[ere] the same but the action was less marke[d]. A sim[ilar] swelling of the fibres was observed together with [the] formation of occasional globular swellings. [The] swelling is also accompanied by an initial incre[ase] in tensile strength rising to a maximum and [then] gradually falling. After four days' incuba[tion], [in] one example, the tensile strength increased from 9·66 to 10·88 and a small but distinct increase [in] affinity for Benzopurpurin was noticed. Prolonged incubation gradually produced a tensile stren[gth] below that of the original, as with *B. subtilis*.

Experiments with other types of bacteria a[re] in progress.

THE SUBMERGED CORROSION OF IRON.*

BY W. G. WHITMAN AND R. P. RUSSELL.

The electrochemical explanation of corrosive action as quite generally accepted soon after its formulation by Whitney[1] and its early development by Walker and other investigators. In more recent years this concept has been severely attacked by proponents of other theories, notably those of direct oxidation[2] and of catalytic colloidal action.[3] The weight of experimental evidence, however, strongly indicates that corrosion is fundamentally electrochemical in nature and that the processes can best explained along electrochemical lines. Certain modifications of the earlier ideas are necessary, and investigations of men who have attacked the electrochemical theory have assisted in clearing up many points and in bringing out the picture which have at present.

Experimental foundation.

Our present knowledge of the facts in submerged corrosion must serve as the basis for any theoretical discussion. Any valid theory of corrosion must adequately explain all the facts given in the numbered paragraphs below. The paragraphs are divided three groups—(1) Natural waters; (2) Alkaline waters; (3) Acids. In Class A of each group are observations which have been repeatedly checked by many investigators, and are matters of common knowledge. In Class B of each group are a series of facts which have recently been observed in this laboratory and in the laboratories of the National Tube Company. These latter observations, although not widely known, have an important bearing on the theory of corrosion.

1. *Ordinary natural waters.*

(1) Dissolved oxygen is necessary for appreciable corrosion of iron or steel at ordinary temperatures, and hydrogen is not evolved except in minute quantities.

The amount of corrosion in a given natural water is proportional to the dissolved oxygen concentration. The rate of corrosion increases with temperature.

Rust formed by the corrosion process is a mixture of ferrous and ferric compounds, the ferrous being adjacent to the metal, and the ferric in the outer layers of the rust film.

The rate of corrosion over long periods of time is different in different natural waters.

(5) The composition or surface condition of the metal has practically no effect on the ultimate rate of corrosion.

(6) Dissimilar metals in contact cause accelerated corrosion on the metal which acts as anode.

B. (1) The amount of corrosion when dissimilar metals are in contact is proportional to the extra surface due to the second metal. That is, if copper is in contact with steel, the total corrosion, though localised on the steel, is the same as if the entire effective area were steel.

(2) Corrosion increases with velocity.

(3) The same initial corrosion rate is obtained in different natural waters, although the ultimate rates are widely different. The rate decreases with time.

(4) Between p_H 4·5 and 9·5 at ordinary oxygen concentrations, the corrosion rate in a given water is constant, and the addition of mineral acid or alkali between these limits has no effect.

(5) The final corrosion rate in natural waters is not influenced by the thickness of the rust film within wide limits.

2. *Alkaline waters.*

A. (1) Corrosion is decreased by increasing the alkalinity.

B. (1) In solutions more alkaline than p_H 9·5 the initial rate of corrosion is the same as in neutral water; this corrosion rate decreases with time to a constant value depending on the p_H.

(2) After a constant low corrosion rate is obtained in alkaline water, if the corroding metal is reimmersed in neutral water, the rate of corrosion increases gradually with time until finally the normal rate for neutral water is obtained.

(3) There is no "critical concentration" of increased corrosion with increasing alkalinity.

3. *Non-oxidising acids.*

A. (1) Corrosion in acids is accompanied by the evolution of gaseous hydrogen.

(2) Increase in acidity (p_H) increases the corrosion.

(3) In contradistinction to natural waters, the composition has a marked effect on corrosion by acids.

(4) The presence of dissolved oxygen increases the rate of corrosion, particularly at high velocities.

(5) Corrosion may be greatly accelerated by dissimilar metals in contact. The acceleration may be much more than proportional to the extra surface.

[3] Carnegie Memoirs, Iron and Steel Inst., 1922, 11.

B. (1) At ordinary oxygen concentrations, the addition of mineral acid does not cause the evolution of hydrogen gas in appreciable quantities until the solution is made more acid than p_H 4·5. With lowered oxygen concentration, however, hydrogen can be evolved at a p_H at least as high as 6.

(2) When the p_H is more acid than 4, corrosion by dissolved oxygen is more rapid than in neutral water.

We believe that these facts are most logically explained along electrochemical lines, as brought out in the following discussion.

General theory

The initial reaction in the submerged corrosion of iron is electrochemical and operates through a corrosion cell. At the anodic electrode of this cell the corroded metal sends ferrous ions into solution according to the reaction $Fe + 2\oplus = Fe^{\cdot\cdot}$ (1). A corresponding reduction* occurs at the cathode area, usually the deposition of hydrogen ions as atomic hydrogen or the solution of dissolved oxygen to form hydroxide ions. The cathode reaction for hydrogen deposition† may be expressed as $2H^{\cdot} = 2H + 2\oplus$ (2), and for oxygen solution as $\frac{1}{2}O_2 + H_2O = 2OH' + 2\oplus$ (3).

Films of corrosion products exert a protective action which depends primarily upon the conditions attending their formation. Even the ordinary rust formed on iron by natural waters exhibits some degree of protectiveness, and certain waters build up more resistant layers than do others. The solubility, density and adherence of the rust film to the metal are vital characteristics. In alkaline solutions, the reason for reduced corrosion is the greater film protectiveness due to decreased solubility of the rust. The effect of neutral salts in the water, while not yet fully understood, is undoubtedly attributable to their action on protective films.

The electrochemical theory is fundamentally based on the conception that the corrosion reactions take place simultaneously at two electrodes. This is in contradiction to the direct oxidation theory, which considers that the oxygen reacts only at the point where the metal is corroding. The latter theory cannot, however, explain the action of other metals, such as copper, in contact with the steel. The advocates of the theory of direct oxidation have failed to appreciate the fact that, although the anode and cathode areas may be widely separated in some cases, in others they may be very closely adjacent as in the corrosion of a single piece of metal. It is entirely possible for a single area to act both as cathode and anode, being cathodic towards another area of higher solution pressure and anodic towards one of lower solution pressure. Furthermore, the products of corrosion or an area protected by a film often act cathodically towards the corroding metal.

With these general considerations, we can proceed to the discussion of the corrosion of iron under different sets of conditions. To assist in this discussion, Fig. 1 has been drawn to show the effect of hydrogen-ion concentration, velocity, and oxygen concentration on the submerged corrosion of iron and steel.

Corrosion of steel vs. hydrogen-ion concentration of solution with varying oxygen concentration and velocity.

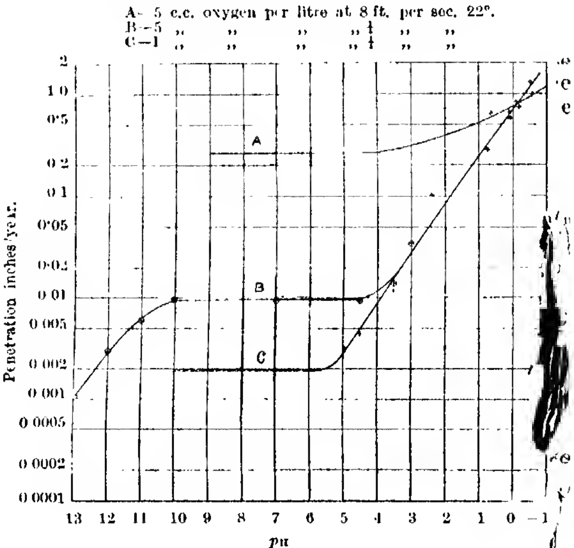

FIG. 1.

The data for this plot have been obtained from the following sources:—Acid corrosion below p_H 2⅟₂ from Whitman, Russell, Welling, and Cochrane.[5] Corrosion at p_H 8, from Speller and Kendall.[6] All other data from Whitman, Russell, and Altieri.[7]

* While these two are the most common cathode reactions there are a number of other reactions possible under very special conditions, such as the deposition of copper, the solution of dissolved chlorine to form chloride ions, and the reduction of nitric acid.

† It should be noted that the oxygen effect has usually been expressed as an oxidation (depolarisation) of the atomic hydrogen formed by reaction (2). Thus Wilson[4] gives the process in the following reactions:— $2H^{\cdot} = 2H + 2\oplus$; $2H + \frac{1}{2}O_2 = H_2O$. If these reactions are written in full showing the hydrogen ion coming from the dissociation of water, they would have the form

$$2H_2O = 2H^{\cdot} + 2OH' = 2H + 2\oplus + 2OH'$$
$$2H + 2\oplus + 2OH' + \frac{1}{2}O_2 = H_2O + 2\oplus + 2OH'$$

By adding the two equations and cancelling 1 mol. of water the reactions reduce to the form

$$H_2O + \frac{1}{2}O_2 = 2OH' + 2\oplus,$$

which is identical with reaction (3) given above. It is thus evident that the net result of Wilson's series reactions is the same as is obtained when oxygen is considered to react directly at the cathode. The authors themselves have used Wilson's equations in earlier papers, but now believe that reaction (3) expresses the facts in a more direct and convenient form, and also allows the direct computation of the electrode potential at the cathode. Furthermore, the corrosion of a metal like copper, which is below hydrogen in the electromotive series, can be more readily visualised on the basis of a direct oxygen electrode reaction than by considering that hydrogen must first be deposited. The situation closely parallels the controversy about the true cathode reaction in the electrolysis of sodium chloride, *i.e.*, does sodium deposit first and then decompose water to form sodium hydroxide and hydrogen, or is hydrogen deposition the primary electrode reaction? This question has been decided in favour of direct hydrogen deposition since the electrolysis of salt can be carried out with less voltage than would be necessary for sodium deposition. Similarly, in the case of oxygen corrosion, the direct oxygen electrode reaction can occur under conditions where atomic hydrogen would not theoretically be deposited unless a depolariser were present.

Corrosion by natural water.

The corrosion of steel by natural waters is almost entirely a question of action by the dissolved oxygen in the water, opposed by the protective action of rust films.

The potential for corrosion of iron by oxygen is so high‡ that it is never the controlling feature in the process. The actual rate of corrosion is limited primarily by two factors: (1) The rate at which dissolved oxygen diffuses into the cathode surface, and (2) the formation of protective films.

The rate of oxygen diffusion is determined by the oxygen concentration, by the distance through which it must diffuse from the main solution to the cathode area, and by the specific resistance of this layer where diffusion occurs. The authors have compared Speller's data (*loc. cit.*) on the corrosion of steel pipe by natural waters and further data of their own with the figures for heat transfer from water to pipe under the same conditions of temperature and velocity. They find that the rate of oxygen diffusion (and hence the rate of corrosion) corresponds to diffusion through a film of quiet water about 0·3 mm. in thickness when the velocity is 0·15 ft. per sec. in a ½-in. pipe at room temperature. It is rather surprising to find that the corrosion rate is fairly independent of the amount of rust on the iron after the initial rust film has been formed. For example, in Cambridge water at 8° C. with a very thin rust film (approximately 1 mm. thick), the corrosion rate was found to be 0·00061 in. per yr. per c.c. of oxygen per litre: after corrosion had continued for three months and the rust film had grown to about 5 mm. thick, the corrosion rate was the same. Now since this rust film may be 5 mm. thick, it must be true that the oxygen does not have to diffuse into the metal but reacts on or just inside the surface of the rust. This would indicate that the rust is itself the cathode surface where oxygen is deposited and OH′ ions are formed.

With this concept the action of protective films (which differs for different waters) may be visualised as follows. The protective film prevents effective electrolytic action between the outside of the rust and the metal, and as a result oxygen must diffuse underneath the surface of the rust film before electrolytic contact is established. Thus the oxygen diffusion is slower when a more protective film is formed, because the path of diffusion to the cathode has been lengthened.*

The corrosion of steel by natural waters containing dissolved oxygen is independent of the hydrogen-ion concentration over a considerable range. Thus if the p_H value of a given natural water saturated with oxygen is varied from about 10 to 4·5 at room temperature by adding sodium hydroxide or hydrochloric acid, the corrosion rate will be unchanged (see Fig. 1). The constancy of corrosion rate with varying p_H is explained by considering the composition of the liquid in direct contact with the metal over this range.

The possibility of a difference in the compositions of the solution in direct contact with the surface of the corroding metal and the main solution itself is a factor which has not received proper appreciation in corrosion studies. Thus, the corrosion of iron in natural water results in the formation of a rust which is highly oxidised to the ferric state on the outside, but which consists of ferrous hydroxide in the inside layers adjacent to the metal. Now ferrous hydroxide is slightly soluble, and because of this solubility, a saturated solution of ferrous hydroxide is somewhat alkaline and has a p_H value of about 9·5. From the solubility product $(Fe^{\cdot\cdot}) \times (OH')^2 = 1{\cdot}6 \times 10^{-14}$, it can be calculated that if the solution against the metal had p_H 7, *i.e.*, if it were absolutely neutral, the ferrous-ion concentration would have to be 1·6 molal before ferrous hydroxide would be precipitated. Similarly, at p_H 6, the saturation value would be 160 molal. We know, however, that ferrous rust is formed in the corrosion of iron by neutral water (containing oxygen) and even by water of p_H 5. It is therefore evident that the solution around the ferrous hydroxide rust cannot have a p_H 5, or even one of 7, since the rust does not dissolve. Hence the p_H of the film liquid must be on the alkaline side as long as any rust is present, even though the main solution may be somewhat acidic.

While the process of intermixing between the main solution and this alkaline film tends to neutralise the film, a fresh supply of ferrous hydroxide is being constantly produced by the process of corrosion. The main solution can therefore effectively neutralise the film only when sufficient acid is diffusing in to equal the production of OH′ ions by corrosion. Now the hydrogen-ion concentration of a neutral solution (p_H 7) is so low that it cannot neutralise the alkaline ferrous hydroxide liquor. Such neutralisation can be effected only by a main solution, the acidity of which is approximately equal to or greater than the alkalinity due to the ferrous hydroxide. This acidity is realised by a hydrochloric acid solution with p_H 4·5, and we find by experiment that this p_H actually marks the limit of the constant natural water range of corrosion, and that hydrogen evolution commences at this point in waters at room temperature which are saturated with oxygen. Solutions of lower oxygen concentration will evolve hydrogen with less acidity, as is shown in Fig. 1, because the rate of ferrous hydroxide production is cut down and it becomes easier to neutralise and dissolve the film. In this connexion solutions of a weak acid, such as carbonic acid, will

‡ The potential of the oxygen reaction at room temperature can be calculated from the normal potentials of oxygen and iron when the ferrous- (or hydroxide- (or hydrogen-)ion concentrations are known, using the ... equation. This method is presented in more detail later for the ... reaction under "Acid corrosion" Fig. 2 shows the oxygen ... plotted against the p_H of the solution for several ferrous-ion concentrations. It will be seen that in saturated ferrous hydroxide solution ... potential is about 1·74 volts, whereas that for the hydrogen evolution ... 0·030 volt (see Fig. 3), thus justifying the assumption that oxygen ... part in the direct cathode reaction rather than acting as a depolariser ... atomic hydrogen. *It should be emphasised that the potential of this reaction is constant, regardless of the alkalinity so long as a saturated hydrogen solution is in contact with the metal.*

* The assumption that corrosion proceeds by the oxidation of ferrous to ferric with the subsequent reaction of this ferric iron with metal to form ferrous, may be the actual mechanism. This is, however, a ... point since zinc apparently corrodes in a similar manner, whereas ... stage of oxidation can exist in its rust film. The correct explanation ... should therefore be general and not specific to iron.

neutralise the film at a lower hydrogen-ion concentration than is required by a strong acid such as hydrochloric acid. The weak acid has a greater total acidity at the same p_H and therefore has a greater neutralising power.[7]

Factors affecting oxygen diffusion.

Since the film protectiveness is maintained constant over the entire natural water range, the rate of corrosion in any given natural water is determined by the rate of oxygen diffusion alone. The composition and surface structure of the iron or steel are of practically no importance, and all commercial steels corrode at the same rate. The work of Hadfield,[8] Richardson,[9] and others has experimentally demonstrated this point.

The factors controlling oxygen diffusion in any given water (*i.e.*, the film protectiveness being constant) are oxygen concentration, velocity, and temperature. The diffusion rate is directly proportional to the oxygen concentration and this is therefore the most important factor in the problem.

The effect of velocity in natural water corrosion is to increase the rate of oxygen diffusion by thinning down the layer of fairly quiet liquid against the surface through which the oxygen must diffuse. Speller's data (*loc. cit.*) on this point are in fair agreement with data on the effect of velocity in heat transfer. In the latter case, it is found that the heat transfer coefficient increases as about the 0·8 power of the velocity of the fluid. The pipe corrosion observed by Speller also increased with velocity at about the same rate. The effect of increased temperature on corrosion by oxygen diffusion is primarily to make diffusion easier because the liquid is more fluid. We find that the temperature effect in heat transfer can be approximated by stating that the rate increases with the 0·8 power of the fluidity of the liquid. It seems probable that a similar relationship holds in the case of corrosion by natural waters, although the data are not yet conclusive.

Alkaline corrosion.

On the alkaline side of p_H 9·5, increased OH′ concentration makes the film liquid more alkaline. The relationship between the concentrations in the film liquid and the main solution is shown in Fig. 3. Solutions which are more alkaline than p_H 9·5 or more acid than 4·5, have a higher ion concentration (OH′ or H˙) than exists in a saturated ferrous hydroxide solution. They, therefore, overbalance the effect of the ferrous hydroxide, and maintain the film liquid at practically the same concentration as exists in the main solution. In the range between p_H 4·5 and 9·5, however, the concentration of either OH′ or H˙ is so low that the main liquor has very little effect on the film and the latter maintains its p_H of 9·5.

The films formed in alkaline solutions beyond p_H 9·5 will therefore be less soluble than those formed in natural water, and the solubility will decrease as the alkalinity increases. From the solubility product of ferrous hydroxide we see that a tenfold increase in OH′ concentration means a 100-fold decrease in the ferrous ion. Films formed in these alkaline liquids will therefore be precipitated more directly and protectively upon the metal surface and the corrosion rate will be reduced. Wilson (*loc. cit.*) and others have attributed the decreased corrosion in alkalis to the very small concentration of hydrogen ions in the solution, using the concept that hydrogen deposition is the first stage in the oxygen reaction. This viewpoint appears entirely untenable on two grounds. In the first place, the potential for either the oxygen or the hydrogen reaction is independent of the alkalinity and the depletion of hydrogen ions cannot be the controlling factor *per se*. In the second place, the type of corrosion result obtained by Speller and Texter[10] and by the authors strongly indicates that the action is one of protective films. Speller and Texter carried out experiments running alkaline solutions through pipes, which have been paralleled by the authors under different conditions. In both cases, it was found that the rate of corrosion in an alkaline solution was initially as high as if the solution were neutral, but that the rate progressively decreased with time, corresponding to the building up of a protective film. Furthermore the authors found that this protective film was readily destroyed when neutral water was substituted for the alkaline solution, and that a considerable time was required before the corrosion rate increased to its normal value for a neutral solution. The character of the corrosion curve with increasing alkali is shown in Fig. 1.

The presence of other film-forming compounds such as sodium silicate gives considerable protection against corrosion at much lower concentration than are required with sodium hydroxide. These materials are finding commercial use as corrosion preventatives.

HE SUBMERGED CORROSION OF IRON.

BY W. G. WHITMAN AND R. P. RUSSELL.

(*Continued from page* 196 T.)

Acid corrosion.

he corrosion of steel in non-oxidising acids inarily occurs with the evolution of hydrogen gas. oxidising acids the cathode reaction is usually duction of the oxidising material, and no hydrogen volved. Corrosion by dissolved oxygen may be important factor in non-oxidising acids, but in hly oxidising solutions its effect is submerged by t of the other oxidising agent. A discussion of hydrogen gas reaction is logically introduced at s point.

he theoretical potential of corrosion with hydrogen lution* is not realised in practice primarily because overvoltage effects which retard and often com-tely prevent the corrosion reaction. The true ure of overvoltage is not fully understood, but ffect is to reduce the available potential. Over-ge varies with a number of factors and is pro-ly influenced by the composition and character metal surface and by the rate of gas evolution. ery[12] gives a value of 0·27 volt for the over-ge on iron in $N/1$ sulphuric acid, but this figure s on commercial steels and must be lower in dilute acids. The latter point is illustrated by act that hydrogen gas can be evolved at atmos-ic pressure and at room temperature in the osion of iron by oxygen-free solutions where p_H is 6 or even greater. Under these conditions theoretical potential would be about 0·2 volt, the overvoltage must therefore be less than this unt.

ydrogen gas is not evolved in detectable amounts the corrosion of steel by neutral waters at room mperature when oxygen is present. Under these nditions the solution next to the metal is saturated ith ferrous hydroxide, the theoretical corrosion tential is 0·030 volt, and the overvoltage is high enough to prevent the formation of hydrogen gas bubbles. It is, however, possible to obtain a very slow evolution of hydrogen under these conditions in the absence of oxygen, since the corrosion rate is too slow to produce enough ferrous hydroxide to maintain a saturated solution against the metal: the theoretical potential therefore is increased. It should be mentioned that hydrogen may be evolved and dissolved directly in the water at pressures much lower than atmospheric, but the rate of such a reaction is necessarily very slow.

The effect of velocity between the metal and the solution on overvoltage is not known with any great accuracy. Velocity certainly does increase overvoltage, as is shown by experiments by the authors[5] where hydrogen gas evolution was decreased by increase in velocity using a steel shaft rotating in sulphuric acid. A probable explanation of this effect is that the gas bubbles are smaller when they are evolved from the rotating electrode and that therefore more energy is required for their formation.

The following data were obtained in experiments[13] to show the effect of oxygen in acid corrosion. Specimens of cold-rolled steel were suspended by glass hooks in bottles containing the corroding agent through which gas was bubbled. Parallel experiments over five-hour periods were made, using oxygen and hydrogen for the comparison. The results are given in Table I.

TABLE I.

Acid.	Conc. % by wt.	Av. penetration, in. per year under O_2.	H_2.	Added corr. due to O_2.	Ratio of $O_2 : H_2$.
H_2SO_4	96	0·079	0·082	−0·003	0·96
H_2SO_4	50	0·262	0·192	0·070	1·36
H_2SO_4	6	0·360	0·031	0·329	11·6
HCl	4	0·482	0·031	0·451	15·5
HCl	0·4	0·388	0·0055	0·383	70·5
HNO_3	1·2	1·82	1·57	0·25	1·16
$CH_3 \cdot CO_2H$	6	0·545	0·0063	0·539	86·5

The last two columns show the added corrosion due to oxygen and the ratio of the corrosions obtained with oxygen and hydrogen. The added oxygen effect is seen to be of the same order of magnitude for all the weaker acids, and the ratio of corrosiveness is very pronounced for the weak hydrochloric and the 6% acetic acids. In the last case corrosion is increased nearly 100-fold by the presence of oxygen. The oxygen effect is slight with the strong sulphuric acid, and is somewhat obscured by the high oxidising power of the nitric acid. Similar data on other metals will be presented in a later paper.

The oxygen effect in acids is greatly increased by velocity due to the increased rate of diffusion. The authors have shown that a rotating steel shaft with a peripheral speed of 10 ft. per sec. will corrode just as

* The corrosion potential of the reaction when hydrogen gas is evolved n be calculated from the normal potentials of iron and hydrogen, recting for ionic concentrations by means of the Nernst equation. The de and cathode reactions in this case are:—$Fe + 2\ominus = Fe^{\cdot\cdot}$; $2H^{\cdot} = 2H + 2\ominus$. is and Randall[11] give the potential of iron against $N/1$ ferrous ion as $Fe^{\cdot\cdot} = 0·441$ volt, using the potential of $N/1$ hydrogen ion against rogen gas (at 1 atmosphere and on platinum) as zero. The Nernst ula for correcting for the ionic concentrations states that a ten-fold ase in ion concentration increases the potential of the metal against olution by 0·058 volt for a univalent ion such as $H^{\cdot}$ and by one-half t amount (0·029 volt) for a bivalent ion such as $Fe^{\cdot\cdot}$. The theoretical otentials of the reaction have been calculated and are shown in Fig. 4, here the potential is plotted against the p_H of the solution for several rrous-ion concentrations. It will be noted that this potential has a onstant value of 0·030 volt for any solution which is saturated with ferrous droxide, *i.e.*, which contains ferrous rust. This must be true, since the e energy of ferrous hydroxide in saturated solution is constant and dependent of the actual concentration.

rapidly in 0·004N sulphuric acid as in 5N acid, provided dissolved oxygen is present, whereas at rest the stronger acid was over ten times as corrosive as the weaker.

Anode and cathode areas.

The conditions which determine whether an area will be initially anodic or cathodic are somewhat indefinite, although the effect of mechanical working is well recognised. On the other hand, the factors determining the anodic or cathodic tendency after corrosion has proceeded are fairly definite. Any area which becomes coated or partially coated with a protective film will tend to become cathodic, and in this same connexion the presence of hydroxide ions is a factor tending toward the formation of protective films.

Theoretical corrosion potential for direct O_2 reaction at 1 atmosphere.

A—Fe''=10^{-6}M. B—Fe''=10^{-1}M.

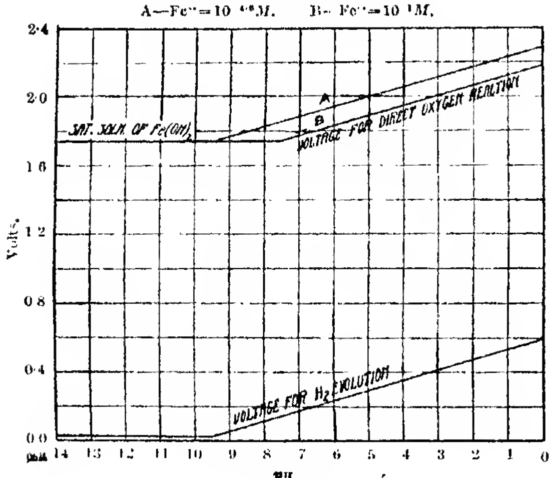

FIG. 2.

Evans'[14] experiments, in which one or the other electrode of a corrosion cell is aerated, are very interesting on this point. He shows that when two pieces of zinc, externally connected, are immersed in a salt solution, either one may act as anode or cathode at the start. If, however, one of the electrodes is removed from the solution, and then re-immersed, it acts cathodically toward the other, and the electrode which has not been removed bears the brunt of the corrosion. The corrosion current can be reversed by aerating the anodic electrode and it, in turn, becomes cathodic. Evans carried out somewhat similar experiments by placing one zinc electrode below the other in the solution. The upper electrode, which was subject to action by dissolved oxygen, became cathodic, while corrosion was mainly located on the lower anode. Furthermore, in this experiment, hydroxide was produced at the upper electrode and soluble zinc salt at the lower. The point at which these two solutions mixed was marked by a screen of precipitated zinc hydroxide. Evans then separated two electrodes by a diaphragm and aerated one of them by a stream of oxygen bubbling through the solution. The oxygenated electrc acted cathodically, and the current set up by t cell was electrochemically equivalent to about 7C of the total corrosion of the two zinc electrodes.

These results are explainable on the basis of t selective formation of protective films at the catho area. The oxygen electrode reaction forms OH' ioı At the same time, a slight amount of corrosion occı on closely adjacent areas and zinc ions are forme These zinc ions precipitate in the alkaline solutic forming a protective coating of zinc hydroxide. the unaerated electrode where no alkali is bei formed, the zinc ions go into solution to form solul zinc salt and no protective film is built up. It important to note, however, that some corrosion do occur at the cathode, and that the action is not 100 corrosion at the anode except under very speci circumstances. Corrosion on the aerated electro occurs because the film protectiveness on the cathoc is not perfect, and short-circuited corrosion cells a set up between points of different potential on tl cathode itself.

In experiments at this laboratory, two externall connected iron electrodes, separated by a diaphragı were immersed in a 5% sodium chloride solutio and oxygen was bubbled past one electrode; it wa found that the oxygenated electrode always reac cathodically under these circumstances, but that ove a 16-hour test, the cathode actually loses twice a much weight as does the anode, showing that twice a much of the corrosion is occurring by means of short-circuited cells on the cathode itself as occurred by cell action between the two separate electrodes. If enough caustic is added to the solution around the unaerated electrode to make it slightly more alkaline than corresponds to a saturated solution of ferrous hydroxide, this electrode then becomes the cathode,

and is practically uncorroded in the test. This would be expected since the alkalinity permits the formation of a protective hydroxide film on the unaerated electrode and hence makes it cathodic. This whole argument may be summed up by the general statement that protective films formed by the corrosion reaction tend to make a given area cathodic and prevent corrosion at that point, whilst the absence of such protective film allows an area to remain anodic.

Theoretical corrosion potential when H_2 gas is evolved at 1 atmosphere.

C. $Fe^{\cdot\cdot} = 10^{-1}$ *M.*

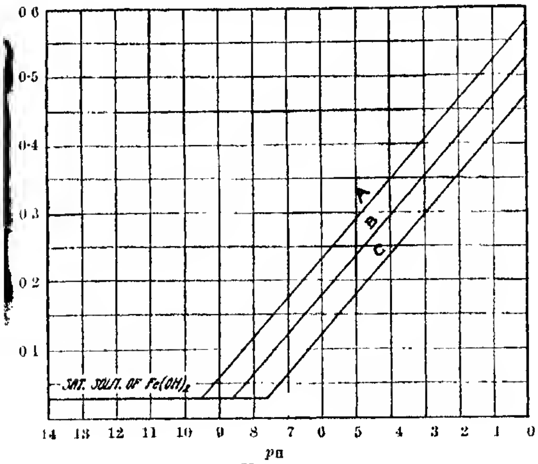

FIG. 4.

Contact of iron with a metal of lower solution pressure, such as copper, increases the corrosion of the iron since the other metal reacts cathodically. In natural waters the effect of copper[15] is to form additional cathode surface to which oxygen can diffuse and react, so the increased corrosion due to the copper is directly proportional to the increase in effective cathode surface and is not the result of any hypothetical catalytic effect. Similar effects are caused by the presence of mill scale, local protective films (such as are formed in very dilute alkali), or other cathodic impurities on steel. These are known to cause severe pitting because the total corrosive action is localised on the unprotected metal, but the results have previously been explained on the basis of catalytic action. In acids, if the metal in contact has a lower overvoltage than that of iron, it makes hydrogen gas evolution much easier and will greatly accelerate corrosion.

If the metal in contact has a higher solution pressure than that of iron, the same considerations are true except that the iron then reacts cathodically and is protected at the expense of the second metal. An exception to this rule occurs when the second metal is non-corroding because of a protective film (as in the case of aluminium).

Summary.

1. The phenomena observed in the corrosion of iron and steel under natural waters and solutions of alkali and non-oxidising acids can be adequately explained along electrochemical lines. Earlier concepts must, however, be modified in the light of our present knowledge.

2. Dissolved oxygen takes part in the direct cathode reaction, rather than serving as a depolariser for atomic hydrogen as postulated by Wilson and others.

3. The rate of corrosion under natural waters is determined by the rate of oxygen diffusion to an effective cathode surface and by the protectiveness of the film formed on the metal. The composition and surface condition of the metal are unimportant factors in the corrosion of ordinary steels and irons. Changes in hydrogen-ion concentration of a given water between approximate limits of p_H 10 and 4·5 do not change the corrosion rate, since the liquid against the metal maintains a constant alkalinity because of the solubility of ferrous hydroxide. The differences in corrosiveness between various natural waters are due to differences in their film-forming tendencies.

4. Under alkalis the rate of corrosion decreases because the rust is more insoluble and hence forms a more protective film. The depletion of hydrogen ions in alkaline solutions, which is given by some writers as the reason for decreased corrosion, is not a factor in the problem.

5. In non-oxidising acids hydrogen gas is evolved and the rate of corrosion by this means is largely affected by overvoltage. For this reason, the composition and surface condition of the metal are important factors. Corrosion by dissolved oxygen in acids is limited by the rate of oxygen diffusion to the surface, as in natural waters. The oxygen effect becomes pronounced in weak non-oxidising acids and at high velocities.

6. The anode and cathode areas may be widely separated or closely adjacent, and any inert area (including rust) in electrical circuit with the corroding anode may act as cathode. Contact with additional cathode area increases the corrosion of iron under natural waters by increasing the area to which oxygen can diffuse. Pitting effects are due to localised corrosion where the unattacked areas have been partially protected (usually by films), and have therefore acted as cathodes towards the corroding pits.

7. The theories of direct oxidation or of colloidal catalytic activity can cover only a part of the phenomena observed in the submerged corrosion of steel. Each is contradicted by certain experimental facts, of which two of the more important are the action of copper in contact with steel under natural waters, and the similarity in the action of oxygen in natural waters and in acids.

Acknowledgment.

Much of the experimental work referred to in this paper was carried out under a fellowship from The National Tube Company, directed by Mr. F. N. Speller. The authors wish to acknowledge the valuable assistance and co-operation afforded by this arrangement.

PROPERTIES OF FUSIBLE ALLOYS.

BY N. F. BUDGEN, M.SC., PH.D.

Previous work on binary, ternary, and quaternary fusible alloys. The expression "fusible metal" is applied to alloys having melting points below that of tin*, so that the alloys falling within this group include binary, ternary, and quaternary mixtures of lead, bismuth, tin, and cadmium. A quinternary alloy, containing in addition mercury, is also classed as a fusible metal. These alloys are used principally in the preparation of readily fusible plugs for use in automatic fire extinguisher systems, but they are also employed for the manufacture of small statuettes and for taking casts of the human body. An important application arose during the war years, when petrol tanks of complicated form were required free from joins and seams for aeronautical work. These were made by electrodepositing copper upon a casting of fusible metal, and then by placing the whole finished article in hot water the fusible alloy was run out, leaving a copper shell intact. Fusible metals used for boiler plugs† are usually of pure tin, since they must have a melting point of not less than 232°.

The melting or freezing point of an eutectic alloy, consisting wholly of eutectic, does not occur over a solidification range, but at some definite temperature, as in the case of a pure metal; nevertheless, owing to surfusion phenomena, the melting and freezing points of such an alloy are not necessarily identical—they are in fact frequently widely different.

If eutectic alloys which alone have a definite freezing and melting point be considered, there are among the fusible metals six possible binary eutectics, four ternary eutectics, and at least one quaternary eutectic alloy.

The eutectie compositions and freezing points of binary fusible alloys are as follows :—

TABLE 1.

Atomic composition % at eutectic.							Freezing point.
Bi	43 0	..	Sn	57 0	..		137 0°
Bi	56 5	..	Pb	43 5	..		125·0°
Bi	55·5	..	Cd	44 5	..		146 0°
Sn	75·0	..	Pb	25·0	..		180 0°
Sn	67·6	..	Cd	32·4	..		177·0°
Pb	63·0	..	Cd	37·0	..		249·0°

The four possible ternary eutectics are given in Table II. :—

TABLE II.

Composition % at eutectic.										Freezing point.
Bi	27·5	..	Sn	33·2	..	Cd	39·3 (atomic)	..		103 0°
Bi	51·65	..	Pb	40·2	..	Cd	8 15(weight)	.		91 5°
Pb	21·0	..	Sn	57·0	..	Cd	22·0 (atomic)	.		145 0°
Bi	52 0	..	Pb	32·0	..	Sn	16·0 (weight)	..		94·0°

Four well-known ternary mixtures, which, however, are not entirely eutectic alloys, are given in Table III :—

TABLE III.

Weight %. Bi.	Pb.	Sn.		Melting point.		Name.
50	31·25	18·75	..	95 0°	..	Newton's alloy
50	28·0	22·0	..	100 0°	..	Rose's alloy
50	25·0	25·0	..	93 0°	..	Darcet's alloy
50	30·0	20·0	..	91·6°	..	Lichtenberg's alloy

Charpy's‡ work on the ternary alloys of lead, tin, and bismuth has shown that all mixtures of the fusible metal group form simple alloys with one another, *i.e.*, they form neither compounds nor solid solutions, but consist of practically pure metals and eutectics. Rose's alloy and Newton's alloy both approximate closely to the composition of the ternary eutectic and melt at about 94°; such alloys are used as soft solder by pewterers. The eutectic alloy of lead, tin, and bismuth possesses the property of expanding on cooling and is therefore used for taking impressions, as the finest details are faithfully reproduced. Bismuth is the component which causes expansion of the alloys on solidification. Other mixtures such as Pb 9, Sb 2, Bi 2, or Pb 10, Sb 1, Bi 1, are often used for stereotype plates, also for casting delicate objects, and for taking impressions from dies, medals, etc. Lastly there are the quaternary bismuth-lead-tin-cadmium alloys and the quinternary mixtures wi mercury, both of which may have an infinite variet of compositions. Two well-known examples a Lipowitz' metal, Bi 15, Pb 8, Sn 4. Cd 3, and Wood alloy, Bi 4, Pb 2, Sn 1, Cd 1, having respective melting points of 70·0° and 60·5°.

Quaternary systems are represented graphically l means of a regular tetrahedron, of which the fo component ternary systems occupy the faces. Th constitutional properties of some part of the quate nary bismuth-cadmium-lead-tin system have bee investigated by Parravano and Sirovich,* who hav discussed the methods of constructing such a figure and of representing the results of thermal analysis i space or on a series of plane sections. These author predicted from mathematical considerations certai of the constitutional conditions which could b expected in an alloy system of this class, and subse quently experimentally verified their results.

The temperatures of solidification of 400 differen alloy compositions were determined and 50 plan sections through the tetrahedral space model we constructed. It seems that the solid solution which are formed at first are completely resolve into their components on cooling, and the observa tions indicate that the solid phases present at th quaternary eutectic temperature are the almos pure metals.

The quaternary eutectic alloy has m.p. 70°, an contains Cd 10·10, Sn 13·13, Pb 27·27, and Bi 49·50 by weight. This composition differs from th assigned to the eutectic alloy by Guthrie,† but a examination of Guthrie's alloy shows it to contai crystals of primary bismuth. It is unlikely that an ternary or quaternary compound is formed, an the development of heat observed in many of th alloys at 95°—100° or 110°—115° is to be attribut entirely to changes in the binary solid solutions, it always diminishes towards the interior of t tetrahedron. A number of typical alloys of low melting and freezing point are given in Table IV and it is seen that several of these have a somewh lower point of initial melting than has the quaterna eutectic alloy. This difference may be due either inaccuracies of temperature measurement or to t influence of surfusion phenomena.

EXPERIMENTAL.

esearch on typical quaternary and quinternary alloys for properties of industrial value.

(*a*) *Temperatures of complete liquefaction and solidification of quaternary alloys.*—For practical purposes, ro definite temperatures are required with regard to sible alloys: the point at which the alloy is first itirely solidified, and that at which it is all quite iid; these temperatures do not therefore corre- ond to the true melting and freezing points.

A series of typical quaternary fusible alloys, with eir supposed melting points, taken from writings Heine, Law, Lassieur and others, are given in ıble V.

TABLE V.

Quaternary fusible alloys.

12	30·8	15·4	38·4	15·4	..		80 0°

ıch of these has been examined with regard to oints of solidification and liquefaction.

The metals used were the commercially pure oducts and contained no appreciable quantities of her elements.

The apparatus employed consisted of a sensitive ermometer reading to 120° and accurate at 100° ıd 0° to within 0·1°; this was surrounded by a otective sheath and entirely immersed in a thin, ırrow-bore test-tube, the intervening space being led with water. The test tube containing the water ıd thermometer was placed inside another test ibe of considerably greater internal diameter, and e space between the large-bore and small-bore tubes ntained the fusible alloy under examination. Each these tubes was of the same length as the thermometer, and when necessary the thermometer was ted partially out of the central tube for examination. he tubes were supported in a large glass beaker led with water. This arrangement allowed for e complete immersion of the thermometer stem, ıus eliminating stem-error and the necessity for lculation of the true value of each reading. The mperature was raised by heating the water in the eaker and lowered by allowing it to cool "naturally." In the neighbourhood of the complete fusion point the temperature of the water bath was raised very slowly so as to ensure obtainment of a true figure. Cooling curves were not taken, but with the thermometer bulb, the alloy in its container was thoroughly and continuously stirred when liquid, until it became entirely solid and no liquid whatever remained. On gradual heating, the point at which the last solid crystals of alloy became liquid was noted, so that at this temperature the alloy was perfectly fluid. By observation and by continuous careful feeling with the thermometer, these definite points could be determined with great accuracy.

The observations made, have established the following thermal data:—

TABLE VI.

Liquefaction and solidification points of fusible alloys.

Alloy no.		Temp. of complete liquefaction.		Temp of complete solidification.

11	..	82 0°	..	68·5°
12	..	85 0°	..	68 0°

* Wood's alloy. † Lipowitz' alloy.

The alloys of lowest complete liquefaction point (73·0°) are seen from the table to be nos. 1 and 9, whilst the mixture of lowest complete solidification point (65·5°) is no. 7.

Most of these fusible alloys have a freezing range, that is, they do not entirely solidify or liquefy at one definite temperature, so that although no members of the series here examined are entirely liquid until 73·0° is reached, certain of them are pasty at a temperature only a degree or two above that of the complete solidification point. It is noticeable that no alloy has been found which melts and freezes at the same temperature, from which it might be inferred that no alloy consisting wholly of eutectic had been examined. This, however, is not necessarily the case, because surfusion phenomena are frequently observed at the solidification of an eutectic; by the simple noting, therefore, of the point of complete liquefaction and solidification, if undercooling has occurred, an eutectic alloy might easily be mistaken for an alloy having a freezing range.

It is well known that during cooling and solidification of an alloy, those portions which have the highest melting point are the first to freeze out, leaving the more fusible constituents until last. This fact was utilised to ascertain whether or not any alloy of lower melting point than those given in the above table could be obtained. Equal proportions of the twelve alloys were melted together in a cylinder with plunger. The mass was allowed to solidify partially, and when only very little liquid remained, this was expressed by means of the plunger. This most fusible constituent of the whole mixture was tested as before, and found to become entirely liquid at 73° and quite solid at 66°, *i.e.*, at no lower point than is shown in the above table.

(*b*) *Temperatures of complete liquefaction and solidification of quinternary fusible alloys.*

The effect of mercury upon the melting points of several fusible alloys has already been studied by earlier workers; for example, Lassieur noted that a mixture Pb 4, Sn 4, Bi 7·5, Cd 1·5, Hg 2, melts at 66°—67°. In the present work the effect has been more thoroughly studied, and to each of the alloys of Table V., 16·6% by weight of mercury was added and the liquefaction and solidification points redetermined as before. The results are tabulated below:—

Mercury fusible alloys.

TABLE VII.

Alloy no.	Temp. of complete liquefaction.	Temp. of complete solidification.
1	68°	56°
2	120°	56°
3	not det.	not det.
4	63°	53°
5	73°	62°
6	70°	56°
7	65°	55°
8	73°	60°
9	63°	50°
10	65°	55°
11	74°	58°
12	68°	61°

Thus it is seen that by the addition of mercury, there is, in general, a lowering of both melting and freezing point, of anything from 5° to 20°.

By adding more mercury the melting points of these alloys can be lowered to any desired degree until the alloy remains pasty or even liquid at room temperature, approximately 50% of mercury being required to bring this about.

Mechanical properties of quaternary alloys.

So far as the author is aware, the mechanical properties of fusible alloys have never before been scientifically determined; figures for hardness, tensile strength, etc. should therefore be of value from the point of view of the manufacture of small casts and statuettes for which fusible alloys are often employed.

Tensile properties of mercury-free alloys.—Specimens of the alloy compositions shown in Table V. were prepared in the form of round rods for tensile testing by drawing the molten metal up into evacuated glass tubing. The metal flowed freely up and quickly solidified, so that in effect chill-castings were obtained. The metal rod was subsequently slipped out of the tube or, in the case of those alloys which expand on solidification, the glass partially cracked of itself and was subsequently removed. The specimens were cut to standard 4-inch lengths and turned in a delicate lathe to 0·188 inch diameter over a 1 inch parallel length. After careful measurement the bars were subjected to tension testing in a Dixon and Hummel wire testing machine; elongation was taken from the 1 inch parallel length. The tests were conducted in duplicate and the average figures are given in Table VIII.

From the table it is seen that the strongest alloy is no. 10, which also shows an elongation of 16% on a 1 inch parallel length; the weakest alloys are nos. 1 and 4.

Alloy no. 1 has a strength of 4422 lb. per square inch, and no member of the series will withstand more than about 3 tons per sq. in. Several of the specimens after tensile testing are shown in Fig. 1.

TABLE VIII.

FIG. 1.

The alloys containing mercury were not tested i tension but were noticed to be much weaker than th above series.

Hardness.—Brinell hardness numbers, obtaine with a load of 500 kg. and 10-mm. ball applied fc 1 minute, are given in Table IX. For the test small cylindrical specimens 1 inch diam. and inch thick were employed; these were chill cast i a metal mould and afterwards polished on opposit faces. The figures are given for both the alloy without and with 16·6% of mercury added; the is seen to be a marked softening by the addition c mercury except in the case of no. 12.

TABLE IX.

These Brinell figures show a maximum value the cases of those alloys which contain the greate proportion of bismuth.

Flexibility.—Nearly all of these fusible allo are extremely brittle under sudden shock loadi yet very flexible and plastic under gradual loadin In both tensile and hardness testing this proper was very marked, for in the tensile testing the res for elongation depended almost entirely upon t

rate of loading and hence upon the rate of straining. The elongation could be made to assume almost any figure by altering the speed of loading, so that to obtain concordant results it was necessary to employ a uniform slow rate of loading for all the specimens.

For instance, in the case of alloy no. 4, by loading in tension a little more quickly than usual, the specimen snapped off like chalk, showing an elongation of about 10%, while by loading somewhat more slowly a value as high as 65% was obtained. Similarly with the Brinell hardness testing, as soon the load had been applied, the lever carrying the ght would begin steadily to sink until resting inst the stop; the load would be then re-applied the sinking continued. In this case also, there-, the time factor was most important if con-lant results were to be obtained. Simple bending s gave further illustration of this remarkable perty: by bending thin rods (¼ in. diam.) very vly they could be formed into any desired shape, by a sharp, quick bending motion the bars would p off short; the alloys indeed behave in this ect exactly like pitch, which is plastic or tle according to the rate of loading. Alloys . 9 and 11 were exceptions and would only bend ough an arc of about 10°.

All of the alloys split on gentle hammering or on ld rolling. Alloys containing mercury exhibited e property of flexibility to a much lesser degree.

Grain size, microstructure, and corrodibility.—Of the loys (Table V.) which contain no mercury, nos. 9, and 11 have the coarsest grain as revealed by a acture; the remainder exhibit a very fine-grained, rey-coloured fracture (see Fig. 2).

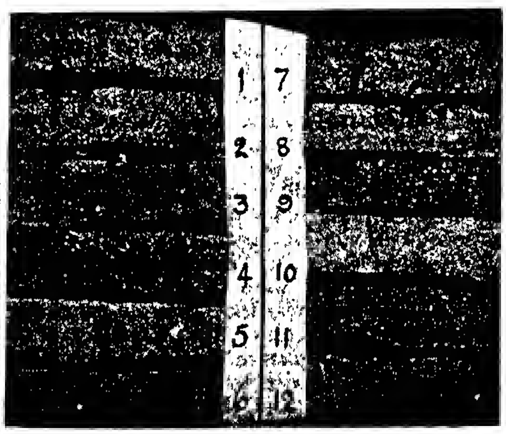

FIG. 2.

The grain size of all specimens containing mercury very fine and close and the fractures are all similar. Micro-examination of representative samples in-icates the existence (in the case of alloys nos. 1 nd 2) of at least four structural constituents, but ese are not easily reproduced photographically. he structure as revealed by casting on glass and ching without polishing is not the true structure of the alloy but represents the form of dendritic growths in contact with the cold glass plate.

The tendency of the alloys to corrode was noted by retaining them molten under water and also under liquid paraffin. After half-an-hour in this state all of the alloys of Table V. formed a quantity of black powdery residue which when stirred would settle rapidly from the liquid, being evidently very heavy. In the case of each alloy, this black residue formed to about the same extent except from nos. 1 and 6, where the amount formed was much greater.

The tendency to corrosion of the same alloys each containing 16·6% of mercury was not more marked.

Summary.

None of the twelve quaternary fusible alloys is entirely liquid until a temperature of 73° is reached, nor is any of them entirely solid above 65·5°. The addition of 16·6% of mercury lowers these points to 63° and 50° respectively, and by further additions the melting point can be reduced so that the alloys are liquid at room temperature.

The tensile strength of the alloys is in no case greater than 3·5 tons per sq. in.; by the addition of mercury this value is much reduced. The elongation can be considerably altered by variations in the rate of loading, and most of the alloys exhibit the property of brittleness under sudden shock and plasticity under gradual loading to a most remarkable degree.

Brinell hardness figures show a maximum value in the cases of those alloys containing the greatest proportion of bismuth.

Grain size, microstructure, and corrodibility have also been studied.

In conclusion, the author wishes to acknowledge his indebtedness to Professor T. Turner, for granting facilities for carrying out the investigation in his laboratories and for his continued interest and advice.

The investigation was conducted in the Metallurgy Department of the University, Birmingham, with financial assistance from the Department of Scientific and Industrial Research.

THE REMOVAL OF GUMMY, OILY, AND WAXY MATTERS FROM RAW CANE SUGAR.

BY C. M. KEYWORTH, M.SC., A.I.C., AND R. B. FORSTER, D.SC., PH.D., F.I.C.

In the filtration of liquors and syrups derived from raw cane sugar considerable difficulty is generally experienced with the gummy, oily, and waxy matters introduced in the raw sugar. Especially is this noticeable when decolorising carbons are used, which are usually indifferent filtering aids. The gums form an impenetrable layer on the face of the filter-cloth, with the result that the filtration efficiency rapidly decreases, the pressure becomes excessive, and the outflow from the press almost negligible.

As is well known, these gums are secretions of the cane plant which protect the stems from the attacks of parasitic insects. The late cane crops contain more gummy matters than the early cane crops, and some types of cane contain much more gummy matters than others, the Uba variety being particularly bad in this respect. Cane wax is also usually present along with the gummy matters. In the process of refining, these gums must be removed, and they cause more or less trouble during filtration.

The gummy matters can be completely removed by the carbonatation process, but this is somewhat costly and cannot always be used economically. There is a growing tendency to try to replace bone-charcoal with activated vegetable charcoal or other activated charcoal, which, although 10–20 times as active as bone-charcoal, yet removes gummy matters very incompletely unless used in excessive amounts, and soon, therefore, causes the rate of filtration to become poor. Filter aids such as kieselguhr ("filter-cel") greatly accelerate the filtering of sugar liquors, but remove little or none of the colour.

It was known to one of us that when steam is blown through a spent filter press which has for some time been used for filtering raw sugar liquors containing decolorising carbons, the press can then be restarted to advantage without stripping. Investigations were made as to the cause of this, and it was found that the gummy, oily, and waxy matters were to a large extent volatile in steam. Hence when a filter press was steamed, the oily film on the cloth was at least partially removed, and the power of filtration restored. The process cannot be repeated indefinitely, as it becomes less effective each time; and, moreover, the steam has a scorching action on the filter cloths.

A sample of raw sugar was dissolved in an equal weight of water in the laboratory, and the solution heated to boiling point *in vacuo* while steam, generated in another flask, was passed through the solution. It was found that the bulk of the gummy matters passed over in the distillate. The residual liquor was then reduced to the same density as the original solution and their rates of filtration were compared. It was found that the rate of filtration of the steam-treated liquor was approximately twice that of the original liquor. Further experiments with raw Peru and Java sugar confirmed this. The gums were not removed quantitatively, but the amount could not be determined, as no completely satisfactory method for this purpose appears yet to have been devised.

The time required to remove the maximum amount of gums naturally depends on the quality of the sugar. Generally speaking, steam was passed through the solution for about half-an-hour, the liquor being maintained at a temperature of 50°–65°, and a vacuum of about 650 mm. used. The density of the liquors was kept at about 60° Brix. To compare the filtration efficiencies, decolorising carbons such as norit and klarit were used, and also filter-cel. In the laboratory trials the increase in efficiency varied from 70 to 100% with most sugars. The decolorising power of an active carbon is greater with a steam-treated sugar liquor, presumably because the pores of the carbon do not become clogged with gummy particles.

By permission of Messrs. Macfie and Sons, Ltd., of Liverpool, experiments were carried out on a large scale in their refinery, and the authors are indebted to them for permission to publish the results. The experiments were made on a sample of raw Peru sugar and washed raw Peru sugar which, though of fair quality, was yet difficult to filter with decolorising carbons. The decolorising carbon used was "klarit," and the filter press a 40-in. washing type plate and frame press.

Four experimental filtrations were carried out: (1) on untreated raw Peru sugar liquor; (2) on treated raw Peru sugar liquor; (3) on untreated washed Peru sugar liquor, and (4) on treated wash[ed] Peru sugar liquor.

Filtration of untreated raw Peru sugar liquor.

Five tons of raw Peru sugar were dissolved to [a] density of 52½° Brix at 66° and 2 cwt. of klarit we[re] added. This liquor was then pumped through t[he] filter-press, and the results recorded in Table I. we[re] obtained. The rate of flow through the press w[as] calculated from the time taken to fill the outfl[ow] trough. After 1 hr. 25 min., since the liquor w[as] trickling very slowly, the flow negligible and t[he] pressure excessive, the press was stopped. The tot[al] amount of liquor run through the press was 6[..] gallons.

TABLE I.

Time in min. after starting press.	Pressure, lb. sq. in.	Rate of flow through press, gall. per min.	Remarks.
4	15–20	—	Frothing badly
6	17–25	—	All taps clear
8	20–27	25·7	—
17	25–35	20·0	—
37	27–42	12·0	—
85	50–60	6·0	—

Treatment of raw Peru sugar by steam in vacuum.—The plant used for subjecting the liquor to treatmen[t] with live steam was a Claassen type vacuum pan. This pan was heated by means of a calandria operate[d] by low-pressure steam, and had a small perforate[d] coil round the inside through which live steam [at] 50–60 lb. pressure could be introduced. This arrang[e]ment was not ideal, but a pan with a larger coil a[nd] low-pressure steam was not available.

Ten tons of the same Peru sugar as used in t[he] previous experiment were dissolved in water a[nd] drawn by vacuum into the Claassen pan. At t[he] beginning of the operation the barometer stood [at] 738 mm and the pressure in the pan at 625 m[m]. The charging of the pan took 29 min., the pressu[re] then being 610 mm. and the temperature and t[he] density of the liquor being 59° and 59° Brix, resp[ec]tively. Steam was then passed in for 90 min., dur[ing] which time the pressure became 635 mm., the te[m]perature 54°, and the density 62½° Brix. The liquo[r] was then diluted to 54° Brix, and pumped to th[e] filtration department.

Filtration of treated raw Peru sugar liquor.

Klarit (2% calculated on the weight of sugar) wa[s] added and the same pumps and press were used a[s] in the previous trial. The pressure rose fairly rapidly

but the flow continued to be very good, and was much greater than in the previous experiment with untreated Peru sugar. After the press had been running for some time, however, it was noticed that the density of the liquor had decreased, owing to the contents of another vessel siphoning through a leaky valve. This vessel was used for washing spent klarit and also contained washings from dirty filter cloths, so that the water therefrom contained a considerable proportion of non-sugars and was difficult to filter. Unfortunately, it was impossible to repeat this xperiment.

The results obtained are recorded in Table II. 'he amount filtered through the press was 1033 gal- ons of liquor, plus the unknown amounts of liquor nd sweet water accidentally introduced as above entioned.

TABLE II.

ime from starting of press, min.	Pressure, lb./sq. in.	Temp. of effluent,	Brix.	Level of liquor from top of tank, in.	Rate of flow, gall. per min.	Remarks.

120	55–75	—	—	44	—	

Filtration of washed Peru untreated sugar liquor.

The same filter press was used, and similar sugar s in the previous experiments, but this sugar was vashed in centrifugals before solution. Klarit (2% n weight of sugar) was added to the liquor. The esults obtained are given in Table III. :—

TABLE III.

ime from starting of press, min.	Pressure, lb./sq. in.	Temp. of effluent,	Brix.	Rate of flow, gall. per min.	Remarks.
5	—	75°	41°	—	Press full
8	10	80°	47°	32·7	—
18	18–20	—	46°	22·5	—
23	20–22	—	46°	22·5	—
31	27–30	—	46°	22·5	—
40	30–40	80°	45·5°	20·0	—
50	35–40	80°	44 5°	17·7	—
60	40–55	—	44 5°	15 3	—
67	40–50	—	44·5°	11·2	—
87	45–55	—	45°	9·0	—

The amount of liquor put through the press was 050 gallons less 175 gallons remaining in the press, hat is to say, 875 gallons.

Treatment of washed Peru sugar by steam in vacuum.
-10 tons of the same washed Peru sugar as used in e previous experiment were then dissolved in water d drawn into the Claassen pan. Steam was passed rough the liquor for a little more than an hour, it owing to the slow rate at which the liquor entered e pan some of the liquor did not get more than minutes' treatment. The final temperature was 5°, and the pressure 635 mm. Water was then lded to bring the density down to 54° Brix. Klarit ·66% on weight of sugar) was added and the quor pumped through the filter-press.

The pump took a long time to fill the press, but fterwards worked satisfactorily. The outflow was uch greater than in the case of the untreated washed 'eru sugar, and the amount put through the press as 1800 gallons.

TABLE IVA.

Time from starting of press, min.	Pressure, lb./sq. in.	Temp. of effluent.	Brix.	Level of liquor from top of tank. in.	Rate of flow, gall. per min.	Remarks.
20	10	77°	44°	—	—	Press full
27	15	—	48°	—	34 0	—
38	22	—	46·5°	—	30 0	—
43	25	—	46·5°	—	27·7	—
49	27	—	46·5°	—	27 3	—
62	32	80°	46°	40	22 2	—
70	30–40	—	46°	—	20 2	Tank almost empty
88	30–40	—	47·5°	54	18·0	

The press was then steamed off, the percentage of klarit brought up to 2%, and a further quantity of liquor run through the press. The results are given in Table IVB.

TABLE IVB.

Time from starting of press, min.	Pressure, lb./sq. in.	Temp. of effluent.	Brix.	Level of liquor from top of tank, in.	Rate of flow, gall. per min.	Remarks.
3	15	71°	48°	—	—	Press full
7	25	—	48°	—	27·7	—
11	25–35	—	47 5°	—	22·8	—
17	30–40	—	47 5°	—	19 8	—
62	35–40	—	47°	32	9·8	—

The amount of liquor run through the press was 1075 gallons, less 175 gallons remaining in the press. Hence the total amount run through the press was 1800, plus 900 gallons = 2700 gallons, compared with 875 gallons with the untreated liquor.

Laboratory control tests were carried out. In the first experiment with raw Peru sugar it was found that inversion occurred to a slight extent during the steam distillation. Thus after one hour's distillation the apparent purity as indicated by the quotient had dropped from 96·76 to 96·71, and when the liquor left the vacuum pan the quotient was 96·45. The acidity per 10 c.c. of the liquor was 2·2 c.c. $N/100$ sodium hydroxide, using litmus as indicator.

In the second experiment with washed Peru sugar the acidity was reduced by the addition of lime to neutrality against litmus, but it was acid to phenolphthalein. Similar inversion, however, occurred, the quotient dropping from 98·59 to 98·26 during the time the liquor was in the pan. It is possible that low-pressure steam would have reduced this inversion to a negligible quantity.

Throughout the steam treatment in the Claassen pan no loss of sugar through entrainment was noticeable.

Conclusions.

The optimum time required for distillation naturally varies with the sugar to be treated, but from 30 to 60 minutes is usually sufficient if the live steam-coil is of suitable proportions. Longer time than this was taken in the large-scale experiments on account of the unsuitability of the steam-coil, and also to ensure that the optimum time had been exceeded, for it would not have been possible to repeat the experiments then. The increase in filtration efficiency is usually about 100%. A more exact statement is impossible, because it is difficult to obtain satisfactory methods of comparing rates of filtration in the laboratory. The viscosity of a sugar solution rapidly decreases as the temperature rises, and it is almost impossible to filter two solutions and keep them at the same temperature. The best

method is to use two suction filters heated in a steam oven and connected to the same filter-pump. Ordinary conical funnels in a steam-oven will, however, give a fair idea of filtration values, though, of course, the amount filtered is small.

The advantages of the method on a commercial scale are numerous and very obvious. Either raw sugar liquors or the partly exhausted syrups—even affination syrups—can be advantageously so treated before filtration. As mentioned above, the decolorising power of a given carbon is increased, because the carbon is not obliged to absorb so large a quantity of gums; but the authors have not yet carried out any quantitative experiments. After treatment by their process the amount of the decolorising carbon required to filter efficiently any sugar-liquor is smaller if the carbon is added for the purpose of filtration, and not for the sake of decolorisation only.

The process is covered by British Patent Application 30,977 of 1923.

α-NAPHTHOLAURIN. A METHOD FOR DETECTING SMALL QUANTITIES OF α-NAPHTHOL IN THE PRESENCE OF β-NAPHTHOL.

BY JOHN EDMUND DRIVER, B.SC., A.I.C.

The preparation of a blue dyestuff by the action of carbon tetrachloride on α-naphthol in alkaline solution is described in British Patent 172,177.

It has been shown (Baines and Driver, Chem. Soc. Trans., 1923, **123**, 1214) that the action of carbon tetrachloride on metallic derivatives of phenol, and of the cresols, results in the formation of aurin or of the corresponding trimethylaurin. In continuing this work the present author has investigated the action of dry carbon tetrachloride on the sodium and potassium derivatives of the naphthols. In the case of α-naphthol, an acid dye is formed. It dissolves in aqueous sodium hydroxide to form a beautiful deep blue solution, from which it is precipitated in flocks on addition of excess of hydrochloric acid. All attempts to crystallise the substance have been unsuccessful, and therefore a sample has not been obtained pure for analysis. However, from previous work (Baines and Driver, *loc. cit.*), there is little doubt that the dye consists chiefly of α-naphtholaurin, $(HO.C_{10}H_6)_2C:C_{10}H_6:O$.

The change in colour from red to blue in passing from the simpler benzenoid aurins to the corresponding naphthol compound is in agreement with common experience in the study of other types of coloured compounds. In confirmation of these views, it is found that β-naphthol, in which the para-position to the central carbon atom is occupied, gives no such dyestuff.

These facts provide a simple method for distinguishing between the naphthols, and also for detecting small quantities of α-naphthol present as impurity in samples of β-naphthol. For pharmaceutical [illegible] other purposes it is essential that β-naphthol should be free from the α-compound, but the usual methods of detection leave much to be desired. The official test of the British Pharmacopœia consists in treating the sample, in boiling aqueous solution, with [illegible] chloride. The precipitate formed should be white changing to brown, and should have no violet tinge showing the absence of α-naphthol (*cf.* Schaeffer Annalen, **152**, 281). This test has the advantage of simplicity, but does not give satisfactory indication of the presence of α-naphthol when the proportion of the latter is very small.

Procedure.—In order to distinguish between the naphthols, 2—3 c.c. of carbon tetrachloride are added to a few milligrams of the sample dissolved in aqueous caustic soda. The mixture is heated on the water bath for ten minutes, preferably with the addition of a little copper powder as catalyst. α-Naphthol gives a pure, deep blue solution, which on exposure to air slowly changes to green. In the case of β-naphthol the solution is pale yellow.

To detect small quantities of α-naphthol in the presence of the β-compound, 0·5 g. of the sample is dissolved in 20 c.c. of 10% caustic soda. 10 c.c. of carbon tetrachloride and a little copper powder are added, and the mixture is heated to boiling for 30 minutes. A blank experiment is carried out with an equal quantity of pure β-naphthol. The two liquids are then filtered through glass wool, and the colours compared in Nessler glasses. The presence of less than 0·005 g. of α-naphthol in 0·5 [illegible] β is sufficient to give the solution a distinct green tinge.

It is essential that the carbon tetrachloride used in these tests should be free from chloroform, since both the naphthols give blue solutions when boiled with chloroform in alkaline solution (Lustgarten Monatsh., **3**, 720).

The author desires to thank Professor F. S. Kipping, F.R.S., for his interest in this work.

A NEGLECTED CHAPTER IN CHEMISTRY: THE FATS.*

BY E. FRANKLAND ARMSTRONG AND JOHN ALLAN.

This account of our knowledge of the fats and of some of the many problems needing study, particularly in the organic branch of chemistry, is mainly written with the hope of reviving interest in them as, part from physical and analytical investigation, no ther province of chemistry has been so little studied ring recent years. This is, no doubt, almost tirely due to the considerable experimental difficules which confront the worker and to the need for aking a mass attack on the subject by the whole aff of a research school during a number of years fore any measure of success can be obtained. It is r intention mainly to consider the subject from the int of view of the origin and the significance of the ts—botanist, chemist, and physiologist alike have interest in this question. We shall strive to licate what has been already established as well the lacunæ in our knowledge. We shall propound estions and seek answers, thereby hoping to imulate the interest of our colleagues.

I.—The Fatty Acids.

As is well known, the natural fats, both animal nd vegetable, are usually triglycerides of straightain fatty acids in which all three hydroxyl groups glycerol are acted upon either by the same or by fferent fatty acids, the product being termed either simple or a mixed glyceride. Fatty diglycerides not normally occur as such, but they may be rmed by fermentative action. The place of one or ore of the fatty acid radicals may be taken, however, an acid of a different kind, as, for example, phosric acid in the case of lecithin. Other alcohols sides glycerol are found associated with fatty acids. ey constitute the waxes, which are mixtures of ers of monohydric alcohols with the fatty acids of h molecular weight and occur as a rule in other rts of the plant than the fats, which are practically nfined to the fruits and seeds. Their function seems be that of protection against water, and not that a reserve energy-producing material. In lecithin e third hydroxyl group of the glycerol is coupled an ester union with phosphoric acid. It will be ar that the opportunity for isomerism and stereomerism in this group is large, and that the number possible arrangements even of such apparently nple materials as glycerol and a few fatty acids is nsiderable.

We are once more brought face to face with the riety which nature is able to evolve from apparently nple materials. We shall use the term fats as covering both the solid fats and the liquid oils; it avoids confusion often present in the lay mind, resulting from the use of the term "oil" for mineral and essential oils.

The fatty acids which occur in nature in the fats as glycerides range from C_4 to C_{24}, inclusive. It is a remarkable fact that only acids with an even number of carbon atoms are present; this fact will be discussed further later.

The waxes contain still higher saturated acids and range from C_{14} to C_{30}.

Both saturated and unsaturated acids occur, some fats—liquid oils—being particularly unsaturated and liable to undergo change. A special class contains an hydroxyl group; in it occur both saturated and unsaturated forms.

Lastly there are the cyclic acids of the chaulmoogric series.

A brief summary of the chemical structure of some of the members of each group seems desirable to facilitate the understanding of the second portion of the paper; it will show the many gaps in our knowledge.

The saturated acids, $C_nH_{2n}O_2$.

The saturated acids call for little comment—they all contain a straight chain of carbon atoms, and no isomerism is possible; they crystallise in one form only, the crystal unit being composed of two molecules arranged end to end with the carboxyl groups adjacent to each other. It is of interest that the synthetic acids containing an odd number of carbon atoms in this series are many of them enantiotropic—they have two melting points and crystallise in two forms. This difference is ascribed by Garner and Randall to alternative methods of arrangement of the two molecules of the acid which go to make up the crystal unit.

The unsaturated acids, $C_nH_{2n-2}O_2$.

Myristoleic acid, $C_{14}H_{26}O_2$, has been isolated by Tsujimoto as a constituent of sperm and dolphin oils, being chiefly responsible for the iodine absorption of the lower fractions of the methyl esters. It is shown to have the structure:

$$CH_3{\cdot}[CH_2]_7{\cdot}CH{:}CH{\cdot}[CH_2]_3{\cdot}CO_2H.$$

It is of interest that the ethenoid bond is in the same position with regard to the CH_3 group as it occupies in oleic acid as well as in erucic acid.

Palmitoleic acid, $C_{16}H_{30}O_2$, is not a common constituent of oils, at any rate in other than very small amounts, but it occurs in greater quantity (17%) in whale oil, from which it can be separated in almost pure state, and to the extent of 12% in skin grease.

* Presidential Address read at the Annual Meeting, Liver ol, July 9, 1914.

It gives a solid iso-acid melting at 21°–22° under the same experimental conditions as oleic acid forms elaidic acid. The position of the ethenoid bond in it is unknown.

Oleic acid.—This acid is characteristic of every fat, and its presence gives to the fats some of their best-known attributes. A number of isomerides are theoretically possible according to the position occupied by the ethenoid bond; there is also the possibility in each instance of *cis-trans* geometrical isomerism.

Several isomeric oleic acids, $C_{18}H_{34}O_2$, have been described, viz :—

(1) Ordinary oleic acid, which has the ethenoid bond in the middle of the chain between carbons 9 and 10, counting the CO_2H group as 1. It has the formula :

$$CH_3{\cdot}[CH_2]_7{\cdot}CH{:}CH{\cdot}[CH_2]_7{\cdot}CO_2H.$$

(2) Hepatic oleic acid, 12:13, was identified by Hartley as having the structure :—

$$CH_3{\cdot}[CH_2]_4{\cdot}CH{:}CH{\cdot}[CH_2]_{10}{\cdot}CO_2H.$$

(3) Iso-oleic acids of unknown constitution are formed during the distillation of commercial stearin or during hydrogenation of oleic acid. Moore has provisionally ascribed an 11:12 ethenoid structure to one of these.

(4) Oleic acid, 2:3, was prepared by Le Sueur from stearic acid.

(5) Elaidic acid, m.p. 44·5°, which is the geometrical solid isomeride of liquid 9:10-oleic acid.

It is customary to describe oleic acid as the *trans* acid for reasons of which we must plead ignorance, though it is usual in other cases of geometrical isomerism, in the absence of any definite evidence, to regard the more stable higher-melting form as the *trans* isomeride, which would therefore lead us to assign this structure to elaidic acid. The latter is obtained by the action of nitrous acid on oleic acid and can be reconverted into it.

In agreement with us, Muller and Shearer as the result of X-ray measurements regard elaidic acid as a *trans* compound. Accordingly the relationship of the two acids is to be expressed by the formulæ :—

$$\begin{array}{ll} CH_3{\cdot}[CH_2]_7{\cdot}CH & CH_3{\cdot}[CH_2]_7{\cdot}CH \\ \qquad\quad \| & \qquad\quad \| \\ \qquad HC{\cdot}[CH_2]_7{\cdot}CO_2H & CO_2H{\cdot}[CH_2]_7{\cdot}CH \end{array}$$

Elaidic—*trans* acid. Oleic—*cis* acid.

The abundant occurrence of oleic acid is no evidence in itself that it is the most stable form in the chemical sense; rather the contrary, in view of its production as the result of chemical changes induced by enzyme action in the living cell. There is no evidence that elaidic acid is a natural product.

(6) Petroselinic acid, said to be oleic acid-6:7, is obtained from parsley. It melts at 33°—34° and is represented as—

$$CH_3{\cdot}[CH_2]_{10}{\cdot}CH{:}CH{\cdot}[CH_2]_4{\cdot}CO_2H$$

It also has a stereoisomeric elaidic form.

(7) Cheiranthic acid, m.p. 30°, is very similar to petroselinic acid: its constitution has not been determined.

Erucic acid, $C_{22}H_{42}O_2$.—This occurs as a glyceride in cruciferous oils, etc.: it has been usually regarded as a *trans* acid but we prefer to assign this structure to the isomeric brassidic acid, and in this view we have again the support of Muller and Shearer. The acids accordingly have the subjoined formulæ, the ethenoid bond being between carbons 13 and 14, that is the same distance from the CH_3 group as in oleic acid.

$$\begin{array}{ccc} CH_3{\cdot}[CH_2]_7 & & [CH_2]_{11}{\cdot}CO_2H \\ & C = C & \\ H & & H \end{array}$$

Erucic acid.

$$\begin{array}{ccc} CH_3{\cdot}[CH_2]_7 & & H \\ & C = C & \\ H & & [CH_2]_{11}{\cdot}CO_2H \end{array}$$

Brassidic acid.

Unsaturated acids, $C_nH_{2n-4}O_2$.

Linoleic (linolic) acid, $C_{18}H_{32}O_2$.—Great confusi[on] is introduced into attempts to determine the stru[c]tural formulæ of this group of acids owing to the[re] being four geometrical isomerides possible of ea[ch] substance. Probably more than one linoleic ac[id] occurs in the animal and vegetable fats, but wheth[er] the isomerism is structural or geometrical cann[ot] be stated.

The accepted formula for linoleic acid is :—

$$\underset{}{CH_3{\cdot}[CH_2]_4{\cdot}\underset{13}{C}H{:}\underset{12}{C}H{\cdot}CH_2{\cdot}\underset{10}{C}H{:}\underset{9}{C}H{\cdot}[CH_2]_7{\cdot}CO_2H}$$

The acids of Chinese and Japanese wood oil, vario[usly] named elæostearic and elæomargaric acid, characterised in particular by the readiness [with] which they undergo oxidation. This suggests [an]other arrangement of the ethenoid bonds in t[he] and the latest constitutional formula suggested

$$CH_3{\cdot}[CH_2]_3{\cdot}\underset{14}{C}H{:}\underset{13}{C}H{\cdot}CH_2{\cdot}CH_2{\cdot}\underset{10}{C}H{:}\underset{9}{C}H{\cdot}[CH_2]_7{\cdot}CO_2$$

Unsaturated acids $C_nH_{2n-6}O_2$.

Linolenic acid with three unsaturated eth[enoid] linkages offers opportunity for still greater isom[erism] and confusion. The formula suggested by Erd[mann] and Goldsobel has the double bonds between ca[rbons] 9 and 10, 12 and 13, 15 and 16. Salway ass[umes] the presence of a grouping :—

$$-\underset{14}{C}H : \underset{13}{C}H{\cdot}\underset{12}{C}H : \underset{11}{C}H{\cdot}\underset{10}{C}H : \underset{9}{C}H-$$

but this conflicts with the formula agreed for l[inoleic] acid. This field invites further investigatio[n] much has to be done first to characterise t[he] saturated acids and their decomposition pr[oducts].

The more unsaturated acids have not [been] isolated: they occur in the oils derived from animals as evidenced in the analyses in Tab[le]

Acids $C_2H_{2n-2}O_3$.

Ricinoleic acid, $C_{18}H_{34}O_3$, is the acidic co[nstituent] of the principal glyceride of castor oil. It [has an] ethenoid bond as in oleic acid between [carbons] 9 and 10 and the hydroxyl group on carb[on]

ɛpressed by the formula :—

$$\begin{array}{l} CH_3{\cdot}[CH_2]_5{\cdot}CH(OH){\cdot}CH_2{\cdot}CH \\ \qquad\qquad\qquad\qquad\qquad\quad \| \\ \qquad\qquad\qquad\qquad\quad HC{\cdot}[CH_2]_7{\cdot}CO_2H. \end{array}$$

It thus occupies an intermediate position between eic and linoleic acids, if it be supposed that the ydroxy compound precedes ethenoid bond for- ation.

It is optically active; nitrous fumes convert it ıto the stereoisomeric ricinelaidic acid.

It remains only to mention the closed-chain acids the chaulmoogric series, which are isomeric with ıoleic acid, but contain only one ethenoid bond.

Mixed glycerides.

Our knowledge of the processes of nature enables to be stated that in all cases selective action is work choosing one form of a substance out of any for further elaboration. Materials, whether ey be proteins or carbohydrate derivatives, c., are made to a definite geometrical pattern most as if they were laid down against an existing mplate. The fats in nature form no exception this rule, the fatty acids being stored in the form mixed glycerides which are asymmetric and fer from one another in the location of a particular tty acid radical in the glycerol molecule.

A diglyceride may thus be either :—

$$C_3H_5\begin{cases} OR_1 \\ OR_2 \\ OR_2 \end{cases} \quad \text{or} \quad C_3H_5\begin{cases} OR_2 \\ OR_1 \\ OR_2 \end{cases}$$

hilst for a triglyceride there are three alternatives :—

$$C_3H_5\begin{cases} OR_1 \\ OR_2 \\ OR_3 \end{cases} \qquad C_3H_5\begin{cases} OR_2 \\ OR_1 \\ OR_3 \end{cases} \qquad C_3H_5\begin{cases} OR_1 \\ OR_3 \\ OR_2 \end{cases}$$

Glycerides, as is well known, are hydrolysed by an ızyme named lipase, but we have no knowledge as to ɔw a given preparation of lipase would behave ards the three isomeric triglycerides represented ɔve. They might be hydrolysed at the same rate, different rates or in stages. In order that such stions can be answered, it appears eminently irable that all these compounds should be prepared l their properties studied.

We are able to report some experiments by C. W. ore on the saponification of fatty acid esters and cerides with alcoholic potassium hydroxide. He ls that the primary esters of the higher fatty acids hydrolysed at the same rate in equimolecular ıcentration, and concludes that the α-mono- cerides of the acids would also be hydrolysed at the ne rate. He was unable to prepare β-mono- rin to compare its behaviour with the α-isomeride ing to internal rearrangement in the molecule ing place, but he was able to show that trilaurin l monolaurin are changed at the same rate and t the hydrolysis does not take place in stages.

It is probable, indeed, that the action of lipase is affected by the nature of the fatty acid radical ept in so far as this may have a secondary influ- : in affecting the nature of the emulsion between yme and glyceride.

The synthesis of glycerides of definitely known structure is complicated by the possibility of internal rearrangement and the wandering of acyl groups in the molecule. Fischer has used acetoneglycerol :—

$$\begin{array}{l} CH_2\text{——}CH{\cdot}CH_2{\cdot}OH \\ | \qquad\qquad | \\ O{\cdot}CMe_2{\cdot}O \end{array}$$

as the starting-point for the preparation of α-mono- glycerides such as α-monolaurin, α-monopalmitin, α-monostearin. These are readily converted into such triglycerides as α-lauro-$\alpha'\beta$-distearin on treat- ment with the corresponding acid chloride and quinoline or pyridine :—

$$\begin{array}{ccc} CH_2{\cdot} & CH{\cdot} & CH_2 \\ | & | & | \\ OA & OH & OH \end{array} \qquad\qquad \begin{array}{ccc} CH_2{\cdot} & CH{\cdot} & CH_2 \\ | & | & | \\ OA & OB & OB \end{array}$$

Under similar conditions the α-iodohydrin gives a diacyl derivative, presumably $\alpha\beta$, which, however, owing to the wandering of an acyl group, changes to the symmetrical $\alpha\alpha'$ derivative :

$$\begin{array}{ccc} CH_2{\cdot} & CH{\cdot} & CH_2 \\ | & | & | \\ OH & OB & OB \end{array} \qquad\qquad \begin{array}{ccc} CH_2{\cdot} & CH{\cdot} & CH_2 \\ | & | & | \\ OB & OH & OB \end{array}$$

On introducing the third acyl group A the final product :—

$$\begin{array}{ccc} CH_2{\cdot} & CH{\cdot} & CH_2 \\ | & | & | \\ OB & OA & OB \end{array}$$

is isomeric with that above, having a higher melting point and lower solubility in accord with its sym- metrical structure.

A method for the preparation of mixed glycerides, in order to be of many-sided applicability, must be of such a nature that the three OH groups of the glycerol can be so differentiated that it is possible to treat them differently at the individual stages of the process; the starting material must, therefore, be such that two of three substitutable groups in the glycerol are at first masked and are uncovered only in the further course of the synthesis and then only successively. A substance fulfilling these require- ments is the compound 2-phenyl-5-hydroxymethylox- azolidine :—

$$\begin{array}{l} HO{\cdot}CH_2{\cdot}CH{\cdot}CH_2{\cdot}NH \\ \qquad\qquad\;\; | \qquad\quad\; | \\ \qquad\qquad\;\; O\text{——}CHPh \end{array}$$

suggested by Bergmann, which has but one alcohol group available for esterification. A second, how- ever, can be produced by the action of acids, whereby it is hydrolysed to benzaldehyde and aminopropylene- glycol, $HO{\cdot}CH_2{\cdot}CH(OH){\cdot}CH_2{\cdot}NH_2$, and finally the third is produced by treating the last compound with nitrous acid.

The actual physical properties of a fat are due to the nature of the glycerides of which it is composed. Two fats may contain the same acid radicals in much the same proportions and yet appear very different in texture, melting point, etc.—factors which are of the greatest importance in their technical applica- tion. Thus analyses of cacao butter and of South American mutton tallow made in our laboratories show that the percentage of fatty acids obtained from

them is very nearly the same and yet the two fats are entirely different :—

	Cacao butter.	Mutton tallow.
Myristic acid	0	1 5
Palmitic acid	23 2	21 0
Stearic acid	33 6	30 0
Oleic acid	41 8	43 0
Linoleic acid	1 4	5 0

Crystallisation from solvents has been the usual means of effecting the separation, but a far more satisfactory method is required. We would go so far as to say that this is the most pressing practical problem awaiting solution in this field of inquiry.

The glycerides in butter fat are mainly mixed glycerides. Oleopalmitobutyrin has been isolated, and it is probable that the whole of the butyric acid found in the fatty acids exists in this form.

The mixed glycerides in lard have been carefully studied by Amberger and Wieschahn, who have compared those isolated with those synthesised and those obtained by their hydrogenation. They have identified the presence of :—

β-Palmito-$\alpha\gamma$-distearin.
β-Stearo-$\alpha\gamma$-dipalmitin.
α-Oleo-$\beta\gamma$-distearin.
α-Palmito-$\beta\gamma$-diolein.
β-Oleo-α-palmito-γ-stearin.

Beef fat contains tristearin, distearopalmitin, and dipalmitostearin (Dekker).

In palm kernel oil, Bömer has identified the presence of the following glycerides :—

Caprylmyristo-olein,	m.p. 14°
Dilauromyristin,	m.p. 33°
Laurodimyristin,	m.p. 40°
Dimyristopalmitin,	m.p. 45°
Myristodipalmitin,	m.p. 51°

Oleodistearin and oleodipalmitin are said to be constituents of cacao butter; in addition it must contain either triolein or glycerides containing two molecules of oleic acid.

II. THE DISTRIBUTION OF THE FATTY ACIDS IN NATURE.

We shall consider the fascinating question of the distribution of the fatty acids in nature under the headings of animal, vegetable, and marine animal fats, etc., adopting this order mainly because it corresponds to increasing complexity. The published information with regard to the fatty acids present in natural fats is scanty, but we are able to include data with regard to a number of fats based on analyses carried out in our laboratories mainly by the ester method by Drs. C. W. Moore, C. H. Clarke, and others during the last twelve years. Until quite recently but little work in this direction has been performed; in future no fat can be considered to have been properly characterised until a full analysis of this type has been made. The method, of course, gives only an approximation, but with much experience comparable, trustworthy results are obtained. Failing the complete analysis, some information as to the composition of a fat is given by the iodine value and saponification equivalent.

Animal fats.

The animal body contains a variety of fats accord ing to the part of the body in which the occur; in addition, the nature of the body fat influenced by the composition of the food which th animal eats. The particular fatty acids taken the food are liable to pass into the body fat and in the milk fat, though the fats themselves are broke down in the processes of digestion to be subsequent reconstituted after absorption. Consequently, cannot be said that each animal is characterised by specific kind of fat, though, inasmuch as most anima live on a diet which is characteristic of the speci it is broadly possible to associate specific qualit with the fat of each animal. Further, abnorn feeding usually means an abnormal body or milk fa hence the variations encountered by the analyst

For example, hogs fed on dried fish yield lard c disagreeable fishy taste, and the modern practice America of feeding hogs on maize is stated to ha produced much softer lards than used to be obtair Similar differences are to be observed with tallo cattle fed on grass on the plains of South America Australia give a harder tallow containing more sa ated fatty acids than those fed on oil cakes wl are richer in olein.

Horses fed continuously on grass or green foo deposit a fat very similar to that of the sheep and whereas the fat of a horse when corn-fed is more oi corn-fed animals give rise to softer fats than t fed on grass.

Fish, which feed on smaller marine animals taining fats of high iodine value, normally conta fat with an iodine value of 110; when fed on mu tallow the iodine value of their fat fell to 79.

Lewkowitsch quotes the following figures :—

Fat from		Iodine val
Rabbit—	wild	101·1
	tame	64 4
Goose –	wild	99 6
	wild, held in captivity 2 years	67 0
	domestic	67 0
Hog –	wild	76 6
	domestic	66 0

as illustrating the very marked influence of d and life habit on the character of the fat. I case of the goose the feeding on fish may expla high iodine value.

In connexion with their researches on vit Channon, Drummond, and Golding have beg study of the alteration in the composition of fat produced by the inclusion of various oils daily diet of cows. The cows were given first a roots and hay diet, then this, plus coconut or a oil, then the basal diet again, then this supple by cod liver oil, and were finally put out to p In all cases the cod liver oil period was marke fall in the fat content of the milk. The ara supplement produced surprisingly little che the analytical characteristics of the fat, but the cod liver oil period the values varied ma showing the passage of the cod liver oil or s its constituents into the milk—the iodine nearly doubled, the saponification value fe 237 to 221.

The fat in the eggs of hens fed on barley had an odine value of about 70; this rose to 97 when nseed was substituted and to 120 with hemp seed. he body fat of the hen in the last instance also had an odine value of 119. However, the fatty acid from ne purified egg lecithin had a normal iodine value, howing that not every fatty acid can enter into the ecithin molecule.

The stored reserve fat of the connective tissues ontains more olein than that of the internal tissues, s for example the fat around the kidneys.

In very fat animals including marine animals the odine value is progressively less in the layers of fat nore remote from the skin, the surface fat consequently containing most olein and having the lowest nelting point. In the hog, Henriques and Hansen bserved the following melting points of the fat :—

At a depth of 1 cm.	33·7°
" " " 2 "	34·8°
" " " 3 "	37·0°
" " " 4 "	39·0°

ch organs as the kidney and liver etc. in which tabolism is active contain fats with a much higher ine value than the connective tissue fat, and rtley has shown that the unsaturated acids contain nbers even of the 2n–6 and 2n–8 series analogous those of the fish liver oils. We shall discuss the ificance of this difference in connexion with the tabolism of the fats, remembering for the moment t the liver is the site of the formation and degradion of fats.

Butter or milk fat is remarkable in that it contains nsiderable amounts of the lower fatty acids volatile a current of steam, in particular butyric acid, ich is absent from the vegetable nut oils. It ntains no acid less saturated than oleic, and only all quantities of stearic acid.

About 30% of the non-volatile acids are composed oleic, but the proportion of this increases as the tation period advances. Human milk fat contains rly 50% of oleic acid and has an iodine value of compared with about 33 for butter. The percene of fat in the milk varies very much with different mals :—

Human	about	3·5
Cow	"	3·5
Dog	"	10·5
Goat	"	4·0
Ass	"	1·3
Pig	"	6·4
Elephant		20
Dolphin		44

The stored fats of the connective tissue, consisting he main of stearin and palmitin, with a proportion olein, all substances relatively stable towards lising agents, are converted in the liver into nly unsaturated, easily oxidised acids with the e number of carbon atoms; this represents an rmediate stage before the break down into simpler ducts, the combustion of which presents no ficulty in the cells of the body. The outstanding rk of Hartley has proved the liver of pigs to ntain the following acids in addition to palmitic l stearic, approximately one half of the acids sent being unsaturated:

1) An oleic acid with the unsaturated link between carbons 12 and 13, which is therefore isomeric with ordinary 9 : 10-oleic acid.

(2) Two linoleic acids, one of which has the unsaturated linkages between carbons 9 : 10 and 12 : 13. Curiously enough no linolenic acid is present. Linoleic acid is present in greater amount than oleic acid.

(3) At least 10% of an acid $C_{20}H_{32}O_2$ with 20 carbon atoms and belonging to the C_nH_{2n-8} series.

Some special explanation seems necessary to account for the presence of this acid, as the saturated arachidic acid is only present in lard in traces at the most and it affords an instance of the synthetic activity of the liver in building up fatty acid chains.

Whilst in herbivorous animals fats are largely formed from carbohydrates, in flesh-eating animals the fat of the food is the usual source of the fat of the body, but it may arise from other materials. Fats are emulsified and hydrolysed in the intestine, the soluble glycerol and fatty acids diffuse into the epithelium cells, where the fats are re-formed and pass *via* the chyle and the blood to the cells of adipose tissue where they are stored. The fat has the same composition here, so far as concerns the identity of its fatty acids, as it had in the food, as is evidenced by the appearance of unusual fatty acids when they are administered in the food.

Obviously mixed glycerides, derived for illustration from cacao butter, will be hydrolysed by lipase in the intestine and the fatty acids recombined in the connective tissues to form quite other simple or mixed glycerides such as are characteristic of the animal.

When the stored fat is required to be utilised it is again rendered soluble in the blood for transportation, the active agent being the enzyme lipase. This enzyme is widely distributed in the body and occurs also in many oil seeds; it has been established that it can act both as an analytic and a synthetic agent. Much remains to be done in studying the distribution and the nature of the activity of the lipase. The liver is the organ which plays the chief rôle in the preparation of the fats for subsequent changes.

The fact that fat may arise from carbohydrate food was first firmly established by Lawes and Gilbert, in their classical experiments on the fattening of cattle and sheep nearly 70 years ago. Whether fats can also arise from proteins is a controversial question. Under abnormal conditions, as for example glucosuria, there is definite evidence that fat is converted into sugar, the seat of conversion being the liver, which is likewise the organ in which the synthesis is effected.

Vegetable fats.

Compounds of fatty acids in the form of fats or waxes are of as frequent occurrence throughout the vegetable kingdom as they are in the animal kingdom. It is to be noted, however, that whilst the fatty glycerides are found in all animal tissues and organs, the same statement cannot be made regarding plants since it is almost without exception in the fruits and seeds that the mixtures of glycerides which constitute the vegetable fats are found. An

example of departure from this is the presence of fat in certain rhizomes, as for instance those of *Cyperus esculentus*.

An outstanding fact in connexion with the vegetable fats is the fixity of their composition The iodine value and saponification equivalent of the commercial oils, of which enormous quantities are used originating from all parts of the world, show a minimum of variation. This is particularly the case with cotton seed oil—the fine breeding to which the cotton plant has been subjected for the purpose of the staple seems reflected also in the constancy of the composition of the oil.

It would appear that the oil contained in seeds is a food reserve for the germinating seed, but it is doubtful if this explanation can be made applicable to such fruits as the olive, that of the West African oil palm, and others, where large proportions of oil are found in the pulpy pericarp, which is separated from the embryo by a hard woody shell and is in all probability dispersed before germination takes place. As a sidelight on its utility or otherwise it may be mentioned that the germination of palm nuts is much more rapid and certain, if the oily pericarp be removed before the nuts are planted.

In other parts of plants, as for instance on the stems and leaves of the *Gramineæ*, in the bark and roots of most trees, and even in the petals of flowers, fatty acids are found combined with a diversity of monohydric and a very few dihydric alcohols in the form of waxes.

This marked difference in composition indicates a provision of the two classes of material for entirely different purposes, and whilst the fats are obviously food reserves, the waxes act as resistants to protect the vegetable tissues from water penetration and the resultant destruction which would follow.

The saturated fatty acids in the vegetable fats are as numerous as those occurring in animal fats (prominently C_6 to C_{22}), but the unsaturated acids are almost wholly C_{18} acids, and their unsaturation is not known to exceed three ethenoid linkages. Probably very small amounts of palmitoleic acid do occur in a number of vegetable fats, but this has not been proved with any degree of certainty.

It cannot be said that plants of the same botanical order yield fats having the same composition, though this is sometimes the case. The *Palmæ* for instance produce nuts very similar in character which yield fats all of which are remarkable for the large percentage of glycerides of low molecular weight which they contain. A considerable number of these fats are found in commerce, and so generally is this fact in their composition recognised that they are frequently classified as "nut oils."

Even from the *Palmæ*, however, fats can be obtained which do not exhibit this special feature, since that obtained from the pericarp of *Elæis guineensis* is the well-known palm oil, a fat having many of the characteristics of and approximating in composition to a soft tallow, whereas the kernel fat is one of the most prominent "nut oils."

This difference in the properties of fats from different parts of the same fruit is not confined to the *Palmæ*, but is also exhibited by members of other orders. Thus the mesocarp of *Stillingia sebifera* (order *Euphorbiaceæ*) yields the well-known solid fat, Chinese vegetable tallow, whilst the seeds furnish a liquid yellow oil having marked drying properties.

In the case of the olive, however, the pulp and kernel fats are very similar to each other when both are extracted from fresh material, but the kernel oil, as usually marketed, is highly rancid, being prepared from residues left after the pulp oil has been extracted.

In a few cases the family to which a plant belongs is indicative of certain characteristics which can be observed, particularly in the composition of the fat in various parts of the seed. A specific example of this is to be found in the genus *Palmæ*, in which the fat of the endosperm is marked by the peculiarity that it always contains an unusually s[illegible] percentage of unsaturated glycerides and a h[illegible] content of glycerides of saturated acids contain[illegible] 10, 12, and 14 carbon atoms. The endosperm [illegible] these fruits is developed in the interior of a h[illegible] woody shell which, in the early stages of the for[illegible]tion of the endosperm, contains a highly sacchari[illegible] liquid, the endosperm itself developing from [illegible] glutinous slime to the hard almost horny con[illegible] in which it is found in the ripe seed. It migh[illegible] expected that the fat in such a seed would be [illegible] similar composition throughout its mass but, [illegible] Richardson has shown in the case of the coco[illegible] this is not so since the fat contained in that port[illegible] of the seed next to the shell, which includes the te[illegible] or thin brown skin which surrounds it, contain[illegible] much higher percentage of unsaturated acids tha[illegible] found in other parts of the kernel. It is proba[illegible] that this difference is due to the presence of a grea[illegible] proportion of olein in that part of the seed, since al[illegible] with an increased iodine value, which is a measu[illegible] of the unsaturation, there is also a marked increa[illegible] in the saponification equivalent, a measure of t[illegible] average molecular weight of the glycerides.

From the examination in our laboratory of a la[illegible] number of coconuts from all parts of the world, [illegible] W. Moore has been able to establish this as a gen[illegible] feature of many varieties of *Cocos nucifera*, [illegible] investigation of the seeds of other members of [illegible] order *Palmæ* would seem to indicate that the pe[illegible]liarity is general. Such highly different palms [illegible] *Elæis guineensis*, which furnishes the West Afri[illegible] palm kernel, and the Brazilian *Attalea*, which is [illegible] source of babassu kernels, exhibit the same charac[illegible]istic feature. The same applies to the kernel of [illegible] Brazil nut, though in a less pronounced degree.

TABLE 1.

Comparison of Oil from the whole Kernel and Kern[illegible] Parings of the Coconut.

	Kernel oil. Sapon. equiv.	Kernel oil. Iodine value.	Parings oil. Sapon. equiv.	Parings oil. Iod. va[illegible]
Malay States	214	7·2	244·2	2[illegible]
Malabar (Cochin)	219	8·7	252·5	4[illegible]
Java	214·5	8·5	253·1	5[illegible]
Celebes Islands	216·5	9·6	249·7	2[illegible]
Philippine Islands	216	7·3	241·8	3[illegible]
Trinidad	216	8·0	246·0	3[illegible]
Fiji Islands	217·5	8·5	237·0	[illegible]

On the other hand an analysis after the s[illegible] manner of the testa obtained from arachis nuts

almonds gave figures indicating an exact similarity between the oil contained in this part of the seed and that in the whole endosperm.

TABLE II.

Comparison of Oil from the whole Kernel and Kernel Parings of various Nuts.

	Kernel oil. Sapont. equiv.	Kernel oil. Iodine value.	Parings oil. Saponif. equiv.	Parings oil. Iodine value.
Palm kernels	231 0	13 5	240 0	29 6
Babassu kernels	221 2	12·2	241·1	22 8
Brazil nuts	289·2	104 8	290 6	114·3
Almonds (sweet)	290 1	101·0	289·4	100·5
Arachis	296 0	97·0	296 0	95 0

The enzyme lipase appears to be absent or at least in a quiescent form in resting seeds, but it develops during germination when the stored-up fat is hydrolysed to fatty acid and glycerol. There is a continuous production of sugar, both sucrose and dextrose, which must come from the fat, the sugar in its turn acting as the antecedent of starch. The work of ... Fürth with sunflower and castor oils has established that, during germination, there is a fall in the molecular weight of the acids as indicated by an increase in the saponification value and a lowering of the iodine and acetyl values. In other words, lower fatty acids are being formed from the higher acids at the expense of the unsaturated linkages and the hydroxylated carbon atoms which constitute the weak points in the chain.

As Gerber has shown, during ripening so long as the seed is soft and green, more oxygen is used than carbon dioxide eliminated. When the seeds become hard and the testa coloured the reverse is the case, more carbon dioxide being eliminated than oxygen used. Finally in the ripe seeds the oxygen intake becomes the greater again. In the olive, which contains mannitol in the unripe condition, this alcohol and protein disappear as fat is formed.

	June 30.	July 30.	Aug. 30.	Sept. 30.
Fat	1 4	5 5	29 2	62 3
Protein	—	—	14 6	4 2

The change from carbohydrate into fat in the case of almonds is exemplified in the following :—

	June 6.	July 4.	Aug. 1.	Sept. 1.
Dextrose	6 0	4 2	0	0
Sucrose	6 7	4 9	2 8	2 6
Starch	21 6	14·1	6 2	5·4
Fat	2	10	37·0	44

It is stated by Russow that in most woody plants starch is in part converted into fat during the winter, the reverse process taking place in the spring. Low temperatures favour the former change; higher temperatures induce the latter.

The investigation carried out by H. L. White on the condition of the oil in soya beans during germination has shown that while the oil is being used for the nourishment of the growing plant the processes of metabolism continue to supply fatty acids of practically the same degree of unsaturation, at least up to the formation of the first set of leaves.

So far as we are aware, the changes in the nature of an oil during the ripening of the seed have been studied in detail in one case only, *viz.*, that of flax or linseed oil, and we are particularly fortunate in being allowed to make reference to certain unpublished results of Dr. J. V. Eyre, which he has communicated to us privately, which are of the highest importance and interest.

Oil formation occurs moderately early in the life of the seed, and proceeds at a rapid rate, amounting approximately to 3% per day on the dry seeds over a period of ten days. The unsaturated nature of the oil of the seed (which is the well-known characteristic of this drying oil) becomes more and more pronounced as the seed advances in age, as evidenced by the following figures :—

Days after flowering.	Oil on dry seeds, %	Iodine value of oil.
10	2·5	114
14	15 1	119
17	31 1	127
23	37	143
28	37	170
35	39	180
51	36 3	190

The greatest rate of increase in the iodine value of the oil takes place after the oil content has attained its maximum value.

The flax seed shortly after fertilisation consists of a white envelope containing an aqueous fluid; during the early days solid material accumulates and the seed swells, becoming green about the 14th day. From this point carbohydrates, oil, and protein are rapidly accumulated and the curves showing the increase in oil and that in carbohydrate and protein combined are roughly parallel. The iodine value of the oil when it first appears is probably as low as 100. Extracts from young seeds have a high fatty acidity which rapidly decreases as the seed ages, showing either that glycerol appears later than fatty acid or that synthesis of the glyceride does not occur immediately.

Marine-animal fats.

The variations in the nature of the body fat of animals according to species, food, and location of fatty tissue has already been indicated. The differences thus created are most strikingly exhibited amongst the fats obtained from marine animals. Even the briefest consideration of their properties necessitates their division into three groups, viz. :—

(1) Fish oils obtained from the bodies of various fish.

(2) Liver oils, obtained from the internal organs, chiefly the liver, of various fish.

(3) Blubber oils, obtained from the fatty tissue of marine mammals.

Our knowledge of these fats is still very incomplete and very much that is published as to their composition must be accepted with considerable reserve. As a class, however, they contain glycerides of certain highly unsaturated fatty acids ($C_nH_{2n-8}O_2$ and $C_nH_{2n-10}O_2$), a fact which clearly distinguishes them from the terrestrial animal and vegetable fats. It is probable that acids containing 18, 20, 22, and 24 carbon atoms exhibit this extreme state of unsaturation, and it would appear also that the characteristic "fishy" odour which is possessed by all of them as generally prepared, is due to the presence of oxidation products of these highly unsaturated glycerides.

The bodies of fish of which the livers are rich in fat rarely contain more than a small percentage of fatty glycerides and the reverse also holds good. The liver fats can generally be distinguished from

TABLE III.

Percentage composition of fatty acids from fats

	C_4	C_6	C_8	C_{10}	C_{12}	C_{14}	−2H	C_{16}	−2H	C_{18}	−2H	−4H	−6H	C_{20}	Average unsaturation in terms of −H	C_{22}	Average unsaturation in terms of −H	C_{24}

acids may be present. It would appear that whatever may be the mechanism of synthesis, there is a tendency to form compounds with 18 carbons, produced it may be from three molecules of glucose, either as such or in the form of the nucleus of starch. The other fatty acids may be formed by secondary reactions from the C_{18} molecule; there would be reason to expect much the same mixture of acids in all fats, at least qualitatively, if the same mechanism were concerned in every case. There is a good deal known about such secondary changes, particularly in relation to the theory of β-oxidation first enunciated by Knoop and subsequently elaborated by Dakin.

If it be admitted that C_{18} acids are derived from starch or from glucose by one of the processes suggested, the method of formation of palmitic acid C_{16} and the higher acids C_{20}, C_{22}, C_{24} requires some consideration.

The summary on page 3 indicates that increasing unsaturation is roughly a function of the length of the chain and that C_{18} acids are not really much more in evidence when other acids are present with them than are the lower and higher members.

Palmitic acid may well be formed as the result of a β-oxidation process, and when palmitoleic and myristic acids accompany it we are inclined to this view. In other cases some mechanism to account for its direct synthesis seems desirable; this we are not yet in a position to suggest.

The formation of higher acids C_{20} to C_{24} is still more difficult to explain—since Hartley found them in the pig's liver derived in all probability from C_{18} acid in the tissues—they may perhaps arise by the condensation of small fractions produced during the oxidation of stearic acid *in vivo*. The location of the ethenoid linkings has to be determined before such questions can be answered.

In vivo, in the animal, the hydrogen attached to the β or the third carbon atom of a fatty acid is selected for oxidation so that a long chain compound loses two carbon atoms every time. For example, phenylvaleric acid becomes phenylpropionic acid and this in turn benzoic acid. Butyric acid is converted first into β-hydroxybutyric acid and then into acetoacetic acid:

$$CH_3{\cdot}CH_2{\cdot}CH_2{\cdot}CO_2H \rightarrow CH_3{\cdot}CH(OH){\cdot}CH_2{\cdot}CO_2H \rightarrow CH_3{\cdot}CO{\cdot}CH_2{\cdot}CO_2H.$$

An exactly similar change is brought about by hydrogen peroxide, as shown by Dakin, when β-keto-acids and the corresponding ketones are formed. This is, however, not the only action of hydrogen peroxide, as there is undoubtedly some oxidation in both the α- and the γ-position. Working with stearic acid Clutterbuck and Raper show that the relative amounts of the acid undergoing β- and γ-oxidation are of the order 7 to 1 respectively. It is suggested that γ-oxidation may also take place in the body, but Dakin considers that all the physiological evidence is against this.

Embden has shown that in the liver acetoacetic acid is only formed from the higher fatty acids with an *even* number of carbon atoms; this is not only a striking confirmation of Knoop's theory, but also indicates that the degradation of the higher acids is progressive, two carbons being split off each time, and that there is no break in the middle of the chain in oleic acid, for example, which might lead to the formation of C_9 units.

A clue to the mechanism of the oxidation of the fatty acids which contain an *uneven* number of carbon atoms is afforded by Ringer's proof that in diabetic organisms they are converted into glucose about in proportion to the amount of propionic acid they might furnish through β-oxidation. According to the evidence, propionic acid is presumably converted into lactic acid or pyruvic acid, and it is well known that the former is quantitatively and the latter partially converted into glucose in the diabetic organism.

The mechanism of β-oxidation has been fully studied by Dakin, who has proved that $\alpha\beta$ unsaturated acids are formed in the animal body either indirectly through the intermediate formation of hydroxy-acids or directly.

In the liver, as Hartley's work has shown, unsaturated acids are formed both from stearic and oleic acids by the introduction of an ethenoid bond between carbons 12 and 13. If oleic acid is formed in nature from stearic, it follows that the ethenoid bond is introduced between carbons 9 and 10 and in linseed, as Eyre has proved, unsaturated acids are formed during ripening. The question arises as to whether these ethenoid bonds are introduced in their final positions at specific points of weakness in the chain of carbon atoms or whether there has been a migration of the bond from some other point where it was first formed to its present position.

It would lead us too far to discuss the migration of ethenoid bonds—a phenomenon well known to the organic chemist—but the conversion of oleic acid into palmitic and acetic acids, together with smaller quantities of lower homologues of palmitic acid on fusion with potash, a reaction involving both oxidation and shifting of the ethenoid link, may be recalled in this connexion.

There is a good deal of evidence known to the organic chemist that acids of a homologous series show an alternation in properties between the odd and even members. This applies to the dibasic acids of the oxalic series as well as to the monobasic fatty acids as Challenor and Thorpe have shown. In the former instance, in addition to differences in physical properties, another property is the ease with which the even members of the series are produced by the direct oxidation of suitable substances, whereas the yield of the odd members is very small, except under carefully regulated conditions, the substance being oxidised to the next lower even number. Thus ricinoleic acid on oxidation with nitric acid yields azelaic acid, $C_9H_{16}O_4$, and suberic acid, $C_8H_{14}O_4$, in about equal proportions, although theoretically only azelaic acid should be obtained. The authors quoted consider that in

district and the centre of what might be called the produce importation of Britain.

With all this going on the citizens of Liverpool had yet time for the other side of life, the higher side—its humanities. The presence of the University, the outcome of magnificent endowments that citizens of Liverpool had bestowed, pointed to the fact that science was not forgotten here. If, as a result of their meeting, the Society could leave a message behind, it should be one of encouragement to the citizens of Liverpool to go on taking an interest in science and all that science means, and to go on taking an even greater interest in the University, if that be possible. Much as Liverpool had done, it was only a tithe of what she would be able to do in the next twenty years if she took advantage of all the facts science could lay at her feet. On behalf of the members of the Society he thanked the Lord Mayor and the Vice-Chancellor for their welcome.

THE KING AS PATRON.

The PRESIDENT recalled the fact that his Majesty the King had very graciously become Patron of the Society on the occasion of the present meeting, and he proposed that the following loyal telegram be sent :—

"Members of the Society of Chemical Industry assembled at the University of Liverpool at their Annual General Meeting beg your Majesty to accept this expression of their gratitude for your Majesty's gracious patronage and this assurance of their loyal devotion. (Signed) PRESIDENT."

This was agreed to with acclamation.

APPOINTMENT OF SCRUTINEERS.

The President announced that Dr. Auden, Prof. Bannister and Dr. C. H. Clarke were willing to act as scrutineers for the ballot for the election of the Council, and it was agreed that they should be appointed as such.

The PRESIDENT formally declared the ballot closed.

HONORARY MEMBERS.

The Minutes of the last Annual Meeting having been taken as read :

The PRESIDENT reported the fact, which had already appeared in our *Journal*, that the Council had added two more distinguished names to their short but very notable list of Honorary Members, namely, those of Dr. Ernest Fourneau and M. Armande Solvay.

M. Fourneau was working at the Pasteur Institute in Paris, and was probably one of the finest manipulators, as a pure organic worker, amongst chemists to-day. His early brilliant work, the production of a lumbar anæsthetic, which with the delicacy of wit so characteristic of France he named Stovaine as a compliment to this country, would be well remembered. His later work, even more remarkable, had been the identification of the "Bayer 205" cure for sleeping sickness and its synthesis. It would be [illegible] the Germans had proposed to keep this remedy secret, contrary to the customary usage of all civilised nations, and to use it as an offensive weapon. The French, thanks to M. Fourneau, had been able to frustrate this action, and the specific would now be available for the use of the whole world. M. Fourneau's work was so remarkable that the Council felt that in honouring him they were certainly honouring themselves.

The name of Solvay hardly required any commendation in Liverpool, and in taking M. Armande Solvay into their ranks they took the head of the great Solvay organisation, the son of a very illustrious father, a man who himself occupied the very highest positio[n] in the great firm, both technical and otherwise M. Solvay's interests in the prosecution of pur[e] science and the encouragement of pure science wer[e] probably well known to many.

Both these gentlemen would have liked to b[e] present at the meeting, but unfortunately they ha[d] been prevented owing to other engagements. F[He] felt sure the meeting would most cordially appro[ve] the selection of these two Honorary Members.

The following Report of Council was taken as rea[d]

REPORT OF COUNCIL.

The Council has the honour to submit to [the] Members the following Report on the activities [of] the Society of Chemical Industry during the y[ear] 1923–24 :—

Membership.

The number of members on the register at Jul[y] 1924, is 4834, as compared with 5060 on June 1923. Since the last Annual Meeting 225 mem[bers] have been elected, 47 former members have [been] restored to membership, and the losses through de[ath,] resignation, etc., have been 498.

The Council regrets to have to record the de[aths] during the past year of the following 40 mem[bers,] of whom 10 were Original Members :—

Dr. G. H. Bailey, Harold J. Bailey, Hu[gh] Barker, Ernest Bentz, Frederick W. Berk, Fr[...] Bloomer, Dr. Charles E. Calm, Edgar V. Cha[...] Dr. Frank Clowes, Louis C. Daniell, F. M. Dick[...] Sir James J. Dobbie, F.R.S., Lincoln W. Eva[...] Farrington, Thomas Fox, Jr., W. H. Francis, J[...] Gall, Robert G. Grimwood, James Hope, A. E. [...]han, Fred Kuttroff, Dr. Albert R. Ledoux, Wil[...] Leonard, Charles Lorleberg, James McAlley, J[...] Mansfield, William E. Moulsdale, Dr. E. K. Mu[...] S. K. Muspratt, William F. Oburg, Edgar Ri[...] F. G. Adair Roberts, Dr. S. P. Sadtler, Fre[...] Seard, Dr. J. E. Stead, F.R.S., George B. [...] William Thomson, Alexander E. Tucker, J[...] Wilkie, and Herbert T. Wilkinson.

Dr. F. Clowes (Original Member) was Pres[ident of] the Society in 1897–98.

During the past three years a considerable [number] of members have had to relinquish their mem[bership] owing to lack of employment, and the Co[uncil have] made arrangements whereby they may resu[me] membership on payment of the current ye[ar's sub]scription only. It is satisfactory to note th[...]

former members have already taken advantage of this concession.

The following table shows the gains and losses in membership during the past five years :—

	1919–20	1920–21	1921–22	1922–23	1923–24
Membership at beginning of year ..	5236	5612	5654	5270	5060
Gains ..	633	472	282	288	272
Losses ..	257	430	666	498	498
Net Gain or Loss	+376	+42	−384	−210	−226
Membership at end of year ..	5612	5654	5270	5060	4834

Honorary Members.

The Council, a year ago, conferred the honorary ·mbership of the Society on the following distin- ished chemists :—

Prince Ginori Conti, Professor C. F. Chandler, ›nsicur Paul Kestner, Prof. J. Sakurai, and Sir J. Tata, and to this list it has now added the mes of Prof. E. Fourneau and Monsieur Armand lvay.

Council.

Dr. E. Frankland Armstrong, F.R.S., retires from office of President at the close of the Annual neral Meeting, and the Council has nominated as successor Mr. W. J. Uglow Woolcock, C.B.E., General Manager of the Association of British emical Manufacturers.

Mr. E. V. Evans and Sir William J. Pope, K.B.E., ve been re-elected Honorary Treasurer and Honor- Foreign Secretary, respectively.

The four Vice-Presidents who retire this year Mr. Julian L. Baker, Mr. C. S. Garland (who will, wever, remain on the Council as Chairman of the emical Engineering Group of the Society), Sir ıx Muspratt, Bart., and Sir Wm. J. Pope, K.B.E., 10 remains on the Council as Honorary Foreign cretary.

To these vacancies the Council has nominated Dr. Frankland Armstrong, F.R.S., Prof. J. W. Hinch- , Prof. J. C. Philip, F.R.S., and Sir Richard relfall, K.B.E., F.R.S.

Four Ordinary Members retire from the Council, d to fill the vacancies thus created six nominations ve been received, and a ballot is being taken, the ult of which will be made known at the Annual eting.

Local Sections.

The following changes take place in the represen- ion of the Local Sections :—

merica : Chairman, Mr. H. S. Miner (*vice*— . R. H. McKee).

irmingham : Chairman, Prof. G. T. Morgan —Dr. E. B. Maxted).

anadian Pacific : Secretary, Dr. R. H. Clark - Mr. J. A. Dawson).

hemical Engineering Group : Chairman, Mr. . Garland (*vice*—Mr. J. A. Reavell).

lasgow : Chairman, Mr. D. A. McCallum (*vice*— W. E. Moodie).

Montreal : Chairman, Mr. J. B. Bell (*vice*—Mr. F. W. Horner). Secretary, Mr. M. C. C. McFee, in place of Mr. C. F. Bardorf.

Newcastle : Chairman, Prof. W. M. Haworth (*vice*—Mr. A. Trobridge).

Nottingham : Chairman, Mr. G. J. Ward (*vice*— Mr. S. F. Burford).

South Wales : Chairman, Mr. W. R. Bird (*vice*— Capt. H. Vivian).

Dr. H. E. Cox, Honorary Secretary of the South Wales Section, resigned in consequence of his removal to London, and Mr. H. W. Webb was elected his successor.

Mr. F. E. Dickie has resigned the Secretaryship of the Shawinigan Falls Section, but his successor has not yet been appointed.

The Council records with great regret the death of Mr. J. M. Wilkie, for many years Honorary Secretary of the Nottingham Section, and who, a year ago, was elected Chairman of the Section. Mr. Wilkie was a keen and energetic member of the Society, and did much excellent work as an honorary official of the Nottingham Section. Mr. S. F. Burford, the previous Chairman, very kindly undertook the duties of the office for the remainder of the session.

The Council desires to convey its cordial thanks to the retiring officers for their services to the Society.

The formation of one or more Local Sections in India has been proposed, with the objects of obtaining new members for the Society, and also as a means of bringing together the chemists of the country and assisting generally in the promotion of the interests of Chemical Industry there.

An Overhead Committee, representative of the Society's membership in India, has been formed to consider the practicability of carrying on Sections at Bombay and Calcutta.

Associates of the Sections.—The scheme under which Local Sections have been permitted to elect students as Associates has been adopted during the year by the Birmingham and Newcastle Sections, and has been found to serve a useful purpose by the Sections who previously took advantage of it. Associates who must be under twenty-five years of age when elected, may continue as Associates until attaining the age mentioned, or for three years, whichever is the longer period. They pay a nominal subscription, and have the right to attend the local meetings, but they have no vote in the affairs of the Section, and do not receive the *Journal*. Many persons elected Associates have subsequently become members of the Society.

Annual Meetings.

At the Annual Meeting of the Society in 1923, held in Cambridge the invitation of the Liverpool Section to hold the Annual Meeting there in 1924 was unanimously accepted.

The Council has received an invitation from its Yorkshire Section to hold the Annual Meeting in 1925 at Leeds and recommends its acceptance.

Messel Medal.

The Council has awarded the Messel Medal for 1924 to the Right Hon. Viscount Leverhulme, and it will be presented to him at the Annual Meeting on the occasion of his delivering the Messel Memorial Lecture. The subject of the Lecture is "Science and Religion."

Finance.

The audited Balance Sheet and Statement of Income and Expenditure account of the Society, and of the Messel Fund for the year ending December 31, 1923, will be laid before the Annual General Meeting.

In view of the continued necessity for exercising the strictest economy, a House Committee, consisting of the President, Hon. Treasurer, Hon. Foreign Secretary, with Mr. Julian L. Baker, Prof. J. W. Hinchley, and Mr. W. J. U. Woolcock (Chairman), has been appointed to control the business affairs of the Society, and to report regularly to the Council.

Journal.

The Council has devoted constant and most careful attention to the development of the *Journal* as a weekly publication. Several economies have been introduced with the result that the expenses of publication have been considerably reduced. The appearance of the *Journal* has been materially improved by the adoption of a uniform paper for all Sections, by a slight increase in the width of the page, and by the substitution of a larger and clearer type in place of that formerly employed.

The *Journal* for 1923 (52 issues) contained 3026 pages of text (Review 1264; Transactions 510; Abstracts 1252) compared with 1958 in 1922 (24 issues), and 1348 pages of Advertisements in 1923, as compared with 918 in 1922.

Some new features have been introduced into *Chemistry and Industry*, with the object of rendering it increasingly attractive and useful to its readers, and it is believed that the development of the correspondence column has proved both interesting and stimulating to chemists generally.

At the inception of the weekly *Journal* the Council was aware that the cost of establishing it on a firm footing would exceed any additional revenue which a weekly journal would produce during its first year, and they therefore temporarily invested £5000 out of income as a development fund to meet the increased outlay. This investment has been sold, and the sum realised has been used for the purpose mentioned.

Bureau of Chemical Abstracts.

An important step was taken in conjunction with the Chemical Society in forming the Bureau of Chemical Abstracts. The Bureau, which has for its aim the unification of British Abstracts now supervises the preparation of the Abstracts in Applied Chemistry, hitherto published by the Society, and those in Pure Chemistry, hitherto published by the Chemical Society, and is under the management of a Committee consisting of representatives of the two Societies. The Society of Chemical Industry is represented by Dr. E. F. Armstrong, Mr. Julian L. Baker, Mr. E. V. Evans, and Sir Wm. J. Pope; the Chemical Society by Dr. Irvine Masson, Prof. G. T. Morgan, Prof. J. F. Thorpe, and Prof. W. P. Wynne, and the Chairman is Prof. J. C. Philip. The Society will bear the expenses of producing and printing the Abstracts in Applied Chemistry during the current year as hitherto, and any expenses common to the two sets of Abstracts will be borne in equal proportion by the two Societies.

Mr. T. F. Burton has been appointed Editor in full control under the Bureau of the preparation and publication of the Abstracts in Pure and Applied Chemistry from the beginning of 1924, and he is assisted in the work by a group of Assistant Editors with special knowledge of the subjects dealt with.

Transactions and Annual Reports.

On the establishment of the Bureau it became unnecessary to continue the services of the Publications Committee, whose work had been chiefly concerned with the Abstracts section of the *Journal* and the Council took the opportunity of conveying to the members of the Committee "the best thanks of the Society for the most satisfactory manner in which they have voluntarily discharged the duties of the supervision and preparation of the *Journal* since its inception, thereby enabling the Society to fulfil one of its prime functions in a manner which has redounded to the credit of all concerned." In particular, mention was made of Messrs. J. L. Baker, W. J. A. Butterfield, C. F. Cross, H. Hemingway, W. R. Hodgkinson, E. Grant Hooper, J. Huebner, C. A. Keane, A. R. Ling, W. Macnab, R. R. Proctor, W. F. Reid, and L. T. Thorne, who have served the Committee for upwards of ten years.

In order to assist in carrying on the publication of the Transactions and the Annual Reports of the Progress of Applied Chemistry, in the meantime a Committee consisting of Messrs. J. L. Baker, W. Coleman, J. W. Hinchley, W. R. Hodgkinson, E. Grant Hooper, W. F. Reid, and W. G. Wagner, was appointed, with Mr. T. F. Burton as Editor.

Leonard Bequest.

Early in the present year, intimation was received that Mr. W. J. Leonard, a member of the Society, who died in September, 1923, had, by a Codicil dated August 19, 1921, to his will directed his trustees to pay to the Society the sum of £5000 as soon as a definite scheme for the provision either by the Society or in conjunction with other Chemical Societies of a building and accommodation to form a central Institute or Club for chemists has been decided upon and is being carried into effect, the decision of the trustees as to whether such scheme has been decided on and is being carried into effect or not to be final and binding upon the Society. In the meantime the income from the Fund will be paid yearly to the Treasurer of the Society for the general purposes of the Society for a period of seven years from the time of the testator's death, or until before the expiration of such period a definite scheme has been decided upon. But if at the expiration of such period of seven years no definite scheme as aforesaid is being carried into effect, then the Trust Fund shall

:o and form part of the testator's residuary estate. The Council decided to open a fund to be called ľhe Leonard Bequest Fund," into which all monies all be paid, including the income from the Trust md.

Chemistry House.

The President (Dr. E. F. Armstrong) shortly there- ter put forward a detailed scheme for the purpose of :uring a home for such of the Chemical organisa- ns as are willing to join together to secure offices the same building, and the Council of the Society nimously authorised him to consult other inter- ed Societies and the Federal Council with a view carrying it at once into effect if it be found prac- able. The scheme has been referred to the Federal uncil, who have appointed a Committee to con- ler it fully.

British Empire Exhibition.

The Society has co-operated with the Association of itish Chemical Manufacturers and other Societies in ganising the Section covering Pure and Applied iemistry, and is represented on the Joint Committee Dr. H. Levinstein, who acted as Chairman of the mmittee, and Mr. E. V. Evans. This Committee has anised the Scientific Exhibit. Under the Chairman- ip of Dr. E. Frankland Armstrong the Publicity ommittee has published a series of pamphlets, ited by Dr. Miall, written in popular language aling with the Scientific Exhibit, and has arranged e publication of "Chemistry in the Twentieth ntury," a scientific record of the state of chemistry the time of the Exhibition as illustrated by the entific Exhibit.

The Council joined in the Scheme promoted by the itute of Journalists for the erection of a stall at Exhibition where Trade and Technical journals ıld be on view, and at this stall (No. 277 in Palace of Engineering) the Society's Journal is played from week to week, along with the Annual orts.

Co-operation.

t is with great pleasure that the Council places record the growth of co-operation between the ety of Chemical Industry, the Allied Societies, other scientific bodies. In particular, it welcomes special arrangement made last year, whereby llows of the Chemical Society could purchase *emistry and Industry* at a considerable reduc- n in price, and a similar arrangement, with newhat altered terms, is in operation during current year. In order to give further facilities each Society to acquire the publications of the other iety a reciprocal arrangement has been entered between the Society of Chemical Industry and Chemical Society, by which members of the mer can obtain the *Abstracts in Pure Chemistry* the price of £1 10s. per annum, and Fellows of the emical Society can obtain the *Abstracts in Applied emistry* for a similar amount.

The scheme arranged between the two Societies der which papers intended for the Chemical ciety may be read at provincial local sections of the Society of Chemical Industry has been success- fully continued during the present year. A similar arrangement has been entered into with the Faraday Society.

Consideration is being given to a proposed scheme under which persons may become members both of the Society of Chemical Industry and the Chemical Society on payment of a reduced total entrance fee.

An arrangement has been made with the Institu- tion of Chemical Engineers for supplying those of its members who are not members of the Society with *Chemistry and Industry* on the same terms as it is supplied to Fellows of the Chemical Society; in return for this the *Journal* of the Society will be adopted as the official organ of the Institution.

A proposal from the Institute of Brewing to share with the Society the expenses of writing and setting-up the Fermentation Section of the Annual Reports of the Progress of Applied Chemistry was approved, and the selection of the author of the Report will in future be a matter of arrangement between the Society and the Institute.

At the request of the British Electrical and Allied Manufacturers' Association, the Council undertook the organisation of the Chemistry and Physics Section of the World Power Conference which is being held at Wembley from June 30 to July 12, and it has deputed the carrying through of the arrangements to the Committee of the Chemical Engineering Group. In addition to the Section mentioned, a Gas and Fuel Section has been added as an outcome of the activities of the Group.

Many joint meetings have been held during the year, both at home and overseas Sections, with other Societies and Institutions.

It has been the custom of the Society for the past two or three years to hold a Dinner for its members in London in the autumn, and last year the scope of the function was widened, the Dinner taking place under the joint auspices of the Society of Chemical Industry, the Chemical Society and the Institute of Chemistry.

Representation on Outside Bodies.

The Society is associated with the activities of many outside bodies through representatives nominated to their Councils. A list of these representatives will be found in the *Journal*. The following recent alterations in the list have to be recorded: Prof. J. W. Hinchley has been appointed on the General Board of the National Physical Laboratory in place of Prof. F. G. Donnan retired, and Dr. R. T. Colgate has been appointed to the Committee on Tests of Graduated Glassware in place of Mr. J. L. Baker, resigned.

Delegates from the Society have attended the meetings of the British Association for the Advance- ment of Science, in Liverpool, 1923; the Annual Meeting of the American Chemical Society, 1924; the International Cement Congress, 1924; the Jubilee Celebrations of the Physical Society of London; the Inauguration of President Stratton at the Massachusetts Institute of Technology, and the National Gas Exhibition at Birmingham.

Dr. E. F. Armstrong has been invited by the Council to represent the Society on the occasion of

the celebration, on June 16, 1925, of the Centenary of the Discovery of Benzene by Faraday in the Royal Institution. He will also attend the Centenary Celebrations of the Franklin Institute to be held in Philadelphia, Pa., in September.

Mr. W. F. Reid will represent the Society at the Kelvin Centenary Celebrations in London in July.

The Empire Sugar Supply (Technical) Committee, formed by the Society of Chemical Industry some years ago, has been re-elected, and Mr. J. L Baker has agreed to act as Chairman in place of Prof. A. R. Ling, resigned.

Latham Research Fellowship.

Through the good offices of Mr. C. F. Cross, F.R.S., the Society received the gift of £300 from Sir Thomas P. Latham, Bart., for the purposes of a Research Fellowship. Two chemists have held the Fellowship in succession for one year each. Mr. James Craik, M.A., B.Sc., the first Fellow, carried out research work at St. Andrews University under the direction of Prof. J. C. Irvine, F.R.S., and the results are embodied in a paper entitled "The Mechanism of the Oxidation of Typical Carbohydrates with Hydrogen Peroxide and Hypochlorous Acid," which, with a prefatory note contributed by Mr. Cross, is published in the Transactions of the Society (1924, pp. 171-177).

Mr. Leslie Hall has worked under the direction of Dr. Charles Dorée at the Borough Polytechnic on the Constitution of Lignone and the Ligno-Celluloses. A paper containing the results of this research is in course of preparation, and will also be published in the Society's Transactions.

The subjects of these researches were selected by Mr. Cross, who has exercised a constant general supervision over the whole of the work.

Grants.

In response to an appeal for a gift of books to the Tokyo Imperial University Library, received from Sir I. Gollancz, it was resolved to make good as far as possible any loss in respect of the Society's publications that the Library may have sustained.

Since the last Annual Meeting of the Society grants have been made to the Chemical Society's Library (£100), and to the British Empire Exhibition, Scientific Exhibit (£500).

Dr. J. T. CONROY, in moving the adoption of the Annual Report of Council, said he thought most members would feel great regret to see that the drop in membership, started two years ago, was still continued. The reason no doubt was that mentioned in the first paragraph, lack of employment, but the efforts made by the Council in improving the *Journal*, including the Abstracts, and in other ways, must appeal to chemists and tend in the long run to increase the membership. He hoped that increase of membership would begin to take place at a very early date. The Council had done very good work for the Society, and the members were all very thankful for their efforts.

Dr. R. S. MORRELL said that the Report showe restless energy on the part of the President and Counc and of all the Officials of the Society. There we several points in the Report that appealed special to him. There was the proposal to grant the form tion of one or more Local Sections in India. T Indian chemists were becoming more and mc active, and we should have the value of their co munications on the raw products of India, to supp ment the excellent reports from the Imperial Institu and the Government. In reference to the *Journ* he felt that the literary character of the articles *Chemistry and Industry* was most stimulati refreshing the reader before he ventured into t narrow strip, sometimes rather stony, of the Trans tions or plunged into the vast forests of the Abstrac He considered that the Abstracts were the best any language whatsoever. There was no ot Society in the section of industry in which he particularly interested which gave such admira Abstracts. He was sure that all members wo welcome the efforts of the President in connex with the proposed Chemistry House. It was institution of an ideal social side, and was alr verging on the millennium. With the Council of Society working in co-operation with other organ tions, it was to be hoped that that ideal would s be realised. The Report contained many insta of valuable co-operation on the part of the Soc with other Societies, as was shown in the ext at Wembley and in many other directions. It to be hoped that the Society would be equ successful in time in settling the designation of ch ists and in clearing up the confusion that now exi between chemists and pharmacists. He had n pleasure in seconding this Report, which he was would be received with hearty appreciation b members of the Society.

Mr. W. CULLEN said that he thought the Co might have issued the Report at least a wee advance of the meeting, in order to give mem the opportunity of reading it beforehand.

As he had pointed out last year, the meeting the one opportunity in the whole year when men met together to discuss the affairs of the Socie a whole. He thought it would be desirable in f years to consider the advisability of devoti little more time to the general meetings of the So These were, after all, the Parliament of the Society.

The PRESIDENT then put the motion to the me and it was carried.

FINANCIAL STATEMENT.

Mr. E. V. EVANS (Hon. Treasurer), in prese the balance-sheet and accounts for 1923 (see *J* of June 27), said that the year had been an ex ingly important one from the point of view of fin The statement of expenditure might be divide two parts, one relating to the management Society and the other to the publication c *Journal.*

With regard to the first he was glad to say th working expenses of the Society for the yea

l been less than in the previous year. It was :essary, however, to deal in some considerable ail with the expenditure upon the *Journal*. He l reported last year that the Council had been icerned at the decreasing revenue from advertise- nts and had decided to put into operation a scheme producing a weekly *Journal*. For this purpose a n of rather over £5000, which had been led to the accumulated fund over the past few ws, had been put aside as a Development Fund the purpose of defraying the initial expenditure connexion with the exploitation and popularisation a weekly Journal. The analysis of the accounts uld show that the total cost of producing the *urnal* last year had been £26,823 as against £21,066 1922. That increased expenditure of £5757 was c to the inclusion of *Chemistry and Industry*.

The extra expenditure of nearly £6000 had been :t from the amount allotted by this Development ınd, together with the revenue from separate sales *Chemistry and Industry*. It would be noticed that : Council has refrained from apportioning a part of : revenue from advertisements to the *Chemistry d Industry* account, although, of course, they uld very justly have done so.

Having dealt with the cost of the *Journal* as a parate item, the analysis of the accounts then came very simple. The revenue to the Society s £500 less in 1923 than in 1922, but the expenses curred by the Society other than those of the *urnal* were £300 less. It would therefore be pected that the excess of income over expenditure uld be about £200 less than last year. That was ually the case. Last year there had been a surplus £580, this year the surplus was £380—the precise ure was £387 17s. 1d.

He did not wish to leave the impression that the ekly *Journal* had been launched with the sole aim ncreasing the revenue from advertisements. The *urnal* of 1922 had been essentially a publication for chemist in industry, and had failed entirely to be ful to that large army of workers who, though rested in chemical matters, were not usually gnated chemists. It was not his place to discuss ther the weekly *Journal* had achieved that, but h a *Journal*, by virtue of its greater popularity, s assuredly a more valuable advertising medium n formerly. The revenue from advertisements s about £800 greater than in the previous year. A ge increase was hardly to be expected in so short a e, but he feared to contemplate to what extent might have decreased had they failed to modify e nature of their publication. The question t would naturally be asked was, "Having nched your weekly *Journal*, what to-day the extent of expenditure in relation to ome ?" In this respect he was pleased to be able report that as a result of having made these itial expenses, as a result of economies in printing d paper, there was every reason to believe that in e present financial year their expenditure would be ... tuned to that justified by their income. ... were realised, the few who persisted in believing that the Society had acted unwisely in shouldering a new burden would have their objection adequately met, and in presenting for adoption the Annual accounts, he suggested that the Society would have failed in its duty had it not increased the scope of the *Journal* to meet the require- ments of an industry which had undergone such rapid development in recent years.

By its action the Society had, with intention, reduced its accumulated fund by £4650, the sum which had been set aside for increasing the value of the Society to members. Had it not done this the Society, he suggested, would have failed to pursue a creative and progressive policy. He referred to the valuable work of Dr. Miall in his contribution to the reduction of printing and paper costs, and also to the excellent work done by the House Committee under the Chairmanship of Mr. Woolcock in controlling the business affairs of the Society. Finally he took this opportunity of thanking the Council for its help and guidance.

Mr. C. S. GARLAND said it was with considerable confidence and with very great pleasure that he had to recommend the adoption of the Report and Accounts to the Annual Meeting. It was, in his opinion, seldom that they had had a more satis- factory financial statement. They had a small balance on the right side. It was perfectly true, as the Treasurer had said, that the Council had used a part of its accumulated fund for the purpose of founding a new weekly *Journal*, which was of the greatest value to the members, and he thought that was an extremely proper course for the Council to have taken.

It must be remembered that the subscriptions of past members and present members were provided for the purpose of advancing the cause of chemical industry in this country. They were not subscribed in order to be put into a banking account so that the members in the future might draw five or four and a half per cent. dividend from Government stocks. They were intended to be used, and the Council was to be congratulated on the step they had taken in using part of the accumulated fund and making the Society of much greater value to its members. There was in the balance-sheet nothing unforeseen. At the last Annual Meeting it had been known that this sum was to be expended for the purpose indicated, and in bringing out a balance-sheet at the end of the year with a small balance to the good, he thought the Society was following in every way the proper course. They ought not to have a large balance to the good, although they did not want a deficit.

There was only one point for regret with regard to the accounts, and that was that members' sub- scriptions had been rather less. But in that con- nexion it must be remembered that industry in this country was still going through a very troublesome time. The chemical industry in particular was still far from being on the upper side of the wave which all were hoping was coming some time in the future, and that being the case there was less employment for chemists in the chemical industry, with the result

that some of the members found it impossible to continue their subscriptions. At the same time there was a satisfactory number of new members coming forward, and from the steps he knew the Council was taking, when the chemical industry improved in this country the income from members' subscriptions would be increased. That was, he thought, the only point, not of criticism but of regret, with regard to the Accounts.

In recommending to the meeting, as he did, with very great confidence, that the Treasurer's Report and Accounts be adopted, he coupled with that a very sincere vote of thanks to their Treasurer, who had had an extremely hard task during the past year. He gave an immense amount of time and work to the affairs of the Society, and he gave at every Council Meeting month by month the fullest record of the progress of the Society's finances. He could say from a knowledge of the inside of the Council that the Council was extremely anxious about the Society's finances. They watched them extremely closely, and an immense amount of work devolved upon our Treasurer in seeing that things were going as he wished. The outcome was the extremely satisfactory balance-sheet before them. In recommending that the Report and Accounts be adopted, he wished to couple with that a very hearty vote of thanks to the Hon. Treasurer for his work during the past year.

Mr. EDWIN THOMPSON wholeheartedly supported everything Mr. Garland has said, and seconded the adoption of the Treasurer's Report and Accounts.

Mr. W. CULLEN said that he had come to the meeting exceedingly depressed by the balance-sheet, but to a certain extent his anxiety had been relieved by listening to the statements of the Honorary Treasurer and Mr. Garland. Last year the expenditure on the *Journal* had been £26,824, and apparently the income from advertisements, subscriptions, and sales had come to £15,128, a net deficit of something like £11,700. Thus the whole of the subscriptions from members last year, amounting to £10,786, plus the entrance fees, plus the life composition fees, all amounting together to about £11,000, had been wiped out. In other words, the whole of the subscriptions had gone towards meeting the deficiency on the publication of the *Journal*. In addition approximately £5000 had been taken from this capital fund, so that the position was really worse than he had shown. On the other hand it was only fair that the membership subscriptions should go a considerable way towards the cost of publishing the *Journal*.

He asked the Hon. Treasurer if he considered we were going to get through the present year without further sacrifice of our capital stocks.

He also asked the Honorary Treasurer if there was no credit to the Chemical Engineering Group account from advertisements? He had understood that there was some off-set against their expenditure in the way of advertising. Further, Annual Reports of Applied Chemistry showed an apparent profit of £48 15s.; he had always understood that the pu tion of these Reports involved loss.

The PRESIDENT pointed out that it had a been the custom of the Society to issue the A Report for the first time at the Annual Me He thought Mr. Cullen's suggestion that it to be in the hands of members earlier was a one. The balance-sheet had been issued i *Journal* of June 27.

The Hon. TREASURER said that the £5000 capital had been put on one side with the s object of developing the weekly *Journal*, as l told the meeting last year at Cambridge. As r the present year, he would not be so unwise as ticipate what was going to happen between nc December, but there was every reason to from the figures which were before them mo month that the income would be nearer the ex ture—they would get very much nearer to a b and would not have to use any monies from account.

Regarding the Chemical Engineering Gro Council had made an arrangement with the whereby a certain sum was allotted each the production of their Proceedings. As the Annual Reports, the figure at which th had been taken was approximately half the price.

Mr. E. GRANT HOOPER said he was sure the n would have welcomed the answer which the T had just given to Mr. Cullen, to the effect thought that next year we should find we dr our reserves to a less extent.

It must not be forgotten in regard to the of the Council, that the members had very fe tunities of conferring together and deciding policy or the men to be placed on the Cour particularly objected to a Council which wa under such circumstances making such an i departure as the publication of a weekly without consulting the Society at large.

The PRESIDENT said that only those who in progress would realise how difficult it wa progress. He put to the meeting the T Annual Report and balance-sheet, which moved and seconded.

The motion was carried.

PLACE OF MEETING FOR 1925.

Dr. L. L. LLOYD extended to the Society invitation to hold its Annual Meeting in I year. This was seconded by Mr. B. A. B the motion carried.

ELECTION OF AUDITORS.

Mr. F. H. CARR proposed the re-election Price, Waterhouse and Co. as Auditors for t year.

Dr. A. C. CUMMING seconded th which was carried

THE PRESIDENTIAL ADDRESS.

The PRESIDENT then proceeded, in the short time maining, to give a very condensed abstract of his residential Address (printed in the *Journal* of uly 11). At the conclusion of the address the ident apologised for having inflicted upon the ting such a technical talk. He was only too conus of having undertaken a task far too difficult to complish in so short a time, but he wanted to cite enthusiasm in these problems, to show how ll of interest they were, how extraordinarily broad ey were, and how many were the aspects and angles n which they could be approached; and, further, wished rather to stress that it was the duty of Society to draw attention to this sort of fundantal problem and to incite progress. Their funcns were to make chemistry go forward, and not stop d say: "We are very proud of what we did fortyee years ago." They must encourage work and gress, and bring home to all the breadth of chemry and promote social progress.

There was never a time when Britain was in more xtreme peril than to-day. The best men, as the sult of the political system, were leaving the untry day after day; every ship that left the port Liverpool carried some of the best artisans, who ere the best because they wished to be unfettered the trammels of custom, would not tolerate ades Unionism, and wanted to go out into the orld where their hands and brains could have full velopment. So long as he was connected with the ciety he should fight to the last for progress.

Dr. LEVINSTEIN said that the President had added e more to the very great obligations which the ciety had already incurred from him by the extrarily interesting and valuable address which just delivered. The Society had had two tal years, in which no doubt they had incurred ms, but it must be admitted that they had made a strenuous effort to widen the scope of the Society.

The President's address was very different from ordinary Presidential addresses, and one which he thought was more appropriate than any to which he had listened or read. He had given them an epitome of the modern chemical industry which, he thought, was extraordinarily useful for those who attended these meetings and were engaged in chemistry.

It was to him most refreshing to listen to Dr. Armstrong at all times, because he was a modern business man and also a scientist, and had therefore acquired proficiency in the scientific principles underlying his business.

It gave him the greatest possible pleasure to propose a very hearty vote of thanks to the President for his most admirable address, and their most grateful thanks to him for the great services which he had rendered to the Society during the two years he had adorned the Presidential chair.

Without the formality of a seconder the vote was carried with acclamation.

The PRESIDENT thanked the members very much indeed for their most kind expression of thanks.

ELECTION OF OFFICERS.

The PRESIDENT reported the result of the ballot with regard to the officers for next year as returned by the Scrutineers.

President: Mr. W. J. Uglow Woolcock.

Vice-Presidents: Dr. E. Frankland Armstrong, Prof. J. W. Hinchley, Prof. J. C. Philip, and Sir Richard Threlfall.

Members of Council: Mr. W. A. S. Calder, Mr. W. H. Coleman, Dr. W. Cullen, and Mr. J. A. Reavell.

INSULIN AND ITS MANUFACTURE.*

BY FRANCIS H. CARR.

Before telling the story of the adaptation of the original laboratory method of making insulin to large-scale manufacture in this country, I wish briefly to describe what insulin—I will not say is, but does.

The nature and use of insulin have aroused widespread interest, and so much has been written and said of them by those better qualified than myself, that it would be presumption for me to undertake this part of my task did I not feel it necessary for my ulterior purpose. Let me first state, however, that I have taken no active part in the investigations but have been, like yourselves, merely an interested and greatly impressed onlooker.

The history of the discovery of insulin has been told many times, and therefore calls for but passing reference. As in nearly every case of discovery, it was not alone due to the work of one man or of one group of men, but to the gradual expansion of our knowledge over a period of many years, that the consummation has at last been reached of practical application in the relief of human suffering.

Painstaking workers in many lands had explored the paths leading there, some without clear vision as to where the paths might lead. They have traversed many devious routes, had bitter disappointments, and in many cases have died before the ultimate fruitfulness of their work could with surety be foreseen.

As the growth of knowledge widens the field it narrows the track and straightens the road for the happy individual who is at length acclaimed a discoverer. In most respects it magnifies rather than belittles such achievement that so many have previously striven in the same direction, and Banting's wonderful discovery seems no less wonderful when we reflect that over 200 years ago the symptoms of diabetes were observed in an animal from which the pancreas had been removed. But it is during the past forty years, since it first became an accepted fact based upon experiment that the removal of the pancreas causes the typical symptoms of diabetes, that the bulk of the work on this subject has been done, and it was not until between two and three years ago that Banting, a new and enthusiastic young worker in this field, achieved the brilliant success of obtaining a stable product from the secretion of the pancreas which, when administered to a diabetic patient, relieved his sufferings and mitigated the disease.

The following quotation from the Report of the Medical Research Council describes more eloquently than I can the effect of this great consummation :—

"The public have become suddenly aware that a substance named insulin has been introduced to use, as is commonly said, 'discovered,' and that daily miracles are being achieved by its means. Men declining quickly or slowly through stages of weal ness and pain to early death have been brougl within a few days back to full working powei sufferers carried to hospital actually dying of diabete already helpless and unconscious, have been resus tated as by some magic and have been brought ba almost at once to normal life, by help of this remed This boon appears as a sudden gift ; diabetic me women and children in these recent months have be granted alleviation which has been denied to their suffering predecessors during all record time."

The introduction of insulin for the treatment *diabetes mellitus* is one of the greatest contributio and, perhaps, even the greatest contribution, e made, to the medical treatment of a specific disea

Once an invention has been made, there rema the important and often difficult task of render the fruits of that invention available for gene enjoyment, of bringing it within the reach of the v rich, of the well-to-do, and, if possible, of the v poor. It is with the last part of the problem t we are chiefly concerned to-day.

The nature of insulin.

Insulin is known only by its effects on the li organism. We have no other method of identif tion or means of determining its purity. It ca the disappearance of some of the sugar containe the blood. We shall better understand what implies if we consider for a moment the part pla by carbohydrates in the living body. All ca hydrates, whether they be taken in the form of st or of sugar, are resolved by the digestive proc to hexoses and of them the glucose is absorbed the blood. This glucose in part directly under oxidation in the blood to meet the energy req ments of the organism, but after partaking of f the digestive process being soon completed, t tends to accumulate in the blood a greater co tration of glucose than can be tolerated therein, in order to accommodate this the surplus is conv into glycogen and stored in the liver and m available for the bodily needs as they arise. amount of sugar in the blood of a healthy man is maintained at about 0·1 % except after a when it temporarily rises to about 0·15 %. actual weight of sugar in the blood varies from 6 to 9 grams.

Should the removal of sugar from the bloo storage or other process not take place for reason, the concentration of sugar there wil above the level of tolerance, and thus caus symptoms of diabetes. When the blood approaches a concentration of about 0·2 % kidneys, which otherwise do not allow the su pass, can no longer prevent its overflowing, sugar is excreted with the urine. Insulin

*Read at the Annual Meeting, Liverpool, on July 11, 1924.

ubstance secreted by the pancreas which has the ffect, when put into the blood stream, of removing ie excess of sugar from the blood of a diabetic, and lso of reducing the blood sugar of a healthy indiıal below the normal. In what way that sugar is oved—in other words, the exact character of the oohydrate metabolism which rapidly follows an ction of insulin into the blood stream—is as yet clear.

s already stated, it is generally assumed that ɔose is made use of by the body either by direct lation or in the building up of glycogen which is ed in the liver and muscles, and it was at first gested that the disappearance of sugar was due direct oxidation to carbon dioxide, but the iratory quotient, in spite of a transitory rise, general falls after the administration of insulin, has experiment shown that the glycogen in the r or muscle is increased. On the contrary, as ı as the insulin has caused the disappearance of ɔose from the blood, it draws upon the glycogen the liver. Dudley and Marrian found that an ılin-treated rabbit actually contained less than normal amount of glycogen in the liver and etal muscle, the figures found being :—

	Normal rabbit. Per cent. glycogen		Insulin rabbit. Per cent. glycogen
Liver	5·53	..	1·86
,eart	0·26	..	0·54
Skeletal muscle	0·57	..	0·00

atever the explanation may be, the facts are :—

1) That an individual suffering from diabetes has an accumulation of glucose in the blood.
2) That insulin is a substance which causes the rapid removal of glucose from the blood.
3) That the symptoms and suffering of a diabetic are greatly relieved by the administration of insulin.

o far little else is known about the chemical perties of insulin, beyond the fact that it possesses property in a very high degree indeed ; 001 gram of the purest insulin so far prepared cause the disappearance of about 3 grams of ar in 2 hours, or 33 grams, but little more than unce, will account for 1 ton of sugar.

t an age when our knowledge of the methods of ıging about change in organic compounds has ome so extensive, it is remarkable to reflect how le is yet known of the oxidative process by which ıble carbohydrate is utilised in the living cell to e free energy and heat, a process which is so ıarkably controlled that our body temperature is intained at the normal temperature with even ater delicacy than that with which we can regulate temperature of so simple a thing as a water-bath h the most delicate thermo-regulating valve. l yet assuredly the oxidation of glucose to carbon xide takes place *in vivo* according to the same emical laws as it does *in vitro*.

So great a volume of work has been done on this xidation in the living subject that we cannot consider it here, but, in passing, attention may be alled to the work *in vitro* now being carried out in he Carnegie Laboratories for Plant Physiology in Tuscon, by which glucose is shown to oxidise to carbon dioxide and water by bubbling air through it in a buffered mixture of the phosphates of sodium in the presence of iron pyrophosphate, which accelerates the change. What a field of fundamental research of great scientific importance remains here for investigation! As in the case of most real research, the difficulties demand great experimental ingenuity and resource. But they do not appear insuperable when we consider the refinements of method and the achievements attained in other fields of research.

One other fact concerning diabetes of interest to chemists must be referred to. Whereas in the normal condition no ketonic substances are excreted in the urine, they may be found in the urine of a person with diabetes, and also in conditions of starvation and in certain fevers. The ketonic substances are acetoacetic acid, $CH_3{\cdot}CO{\cdot}CH_2{\cdot}COOH$, and acetone, $CH_3{\cdot}CO{\cdot}CH_3$. There is frequently also present what is obviously the parent substance of these two compounds, namely, hydroxybutyric acid, $CH_3{\cdot}CH(OH){\cdot}CH_2{\cdot}COOH$. These substances result from the oxidation of fats. Not only, therefore, is a diabetic unable to dispose of all his carbohydrate, but his fat is not oxidised to the normal end-product. Insulin treatment causes the rapid disappearance of acetoacetic acid as well as of sugar from the urine. It has been suggested that it acts primarily upon the sugar metabolism, and that fat metabolism cannot proceed normally without simultaneous occurrence of the former process, but we have to await the final elucidation of this and a host of other problems of a similar nature. The discovery of insulin has given a new and very valuable method of investigating body metabolism, and opens out a vast field for research.

While insulin is necessary to prevent the accumulation of sugar in the blood beyond the point at which the sugar, so to speak, becomes harmful to the body and interferes with the cell processes, on the other hand too much insulin reduces the sugar to a minimum figure and acts as a poison, causing severe symptoms and ultimate death.

There is, moreover, stored in the pancreas of a normal person insulin much more than sufficient to cause death were it all released from the cells in which it is stored and allowed to enter the blood stream. Insulin appears to exercise its effect in a fixed quantitative ratio; in other words, a given amount of insulin always causes the disappearance of the same quantity of sugar. Since in a normal animal the amount released is so regulated that the blood sugar is quickly brought to a basal level, it follows that the mechanism of release is such that it is stimulated by an increase of blood sugar above the normal. Directly or indirectly, then, an excess of glucose above the basal level in the blood stimulates the release of insulin.

The story of the remarkable activity of insulin in causing the removal of sugar is more wonderful than all that is written in "The Arabian Nights," and when we consider in addition to this the delicate mechanism by which increased amounts of sugar can

set free insulin and in the correct amount, we chemists are indeed lost in wonderment and awe.

If the mechanism of this release failed to act, diabetes would result through there being a deficiency of insulin in the blood, but it is more commonly supposed that diabetes is caused by the failure of the pancreas to form insulin. The question which of these is the real cause still awaits experimental solution.

One of the properties of insulin is that it is very sparingly soluble in water at its iso-electric point, namely p_H 5·2. A small adjustment of the hydrogen-ion concentration either to the acid or the alkaline side of this iso-electric point renders it readily soluble, and it seems likely that the release of insulin from the cells to the blood is controlled locally in the tissues in which it is stored by minute variations of the hydrogen-ion concentration of the body fluid at that point.

Chemical properties of insulin.

The properties of insulin thus far observed are as follows :—As already stated, it is sparingly soluble in water at its iso-electric point, but readily soluble at other points near neutrality. It is precipitated by half saturation with ammonium sulphate and sodium chloride, and by picric acid, phosphotungstic acid, and trichloroacetic acid, and is insoluble in absolute alcohol. As prepared from the ox pancreas it gives a distinct biuret reaction, but Best and Macleod obtained no such reaction with insulin prepared from the skate pancreas. The purest insulin has given negative reactions for phosphorus, tryptophan, and tyrosine, whilst all samples give a well-marked reaction for organic sulphur.

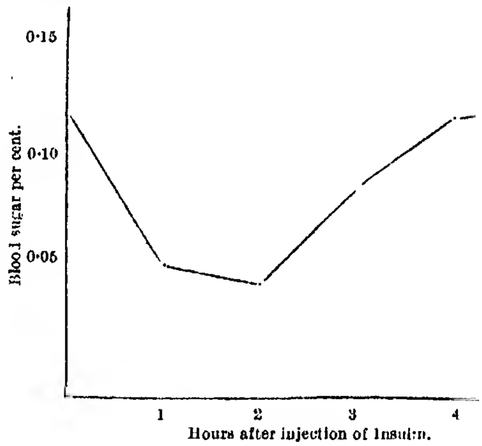
It is almost completely destroyed by $N/10$ sodium hydroxide at 37° in $1\frac{1}{2}$ hours, and is destroyed by $N/10$ sodium carbonate in boiling water in about 10 minutes. Even in neutral solution it is destroyed at 100° in about 10 minutes, but in $N/10$ acid it is not quite completely destroyed at this temperature even after one or two hours.

The active principle will not pass through an ultra-filter of collodion but can be filtered through a porous pot at reactions wide of the iso-electric point. Since both pepsin and trypsin destroy it, it is apparently of protein-like structure.

From the foregoing it is obvious that insulin is a substance of considerable complexity.

Insulin may be determined quantitatively with considerable accuracy by observing its effect on the blood sugar of normal animals. Rabbits and mice have chiefly been used for this purpose. Sufficient insulin will naturally be present in an animal for its normal requirements. If a rabbit is kept for 24 hours without food, it is brought more or less to a standard condition as regards glycogen storage and the amount of sugar in the blood. Under these conditions the blood sugar will be about 0·10%. If a moderate dose of insulin is administered intravenously or subcutaneously, the percentage of sugar in the blood falls and then recovers after several hours, reaching its minimum between one and three hours. The following curve will illustrate what happens.

The amount and time of endurance of represented by the area i n the curve varie tionately to the amount of insulin adm Rabbits, however, have individual variatio the same dose has not identically the sa on different rabbits. The reaction of an i rabbit may also change from time to ti inaccuracies thus introduced are minimised a number of animals for any one test. at first adopted was based upon the ar insulin required to lower the blood su 0·10 to 0·045% within four hours in weighing 2 kg. and after 24 hours' fa follows, however, from what has been said variation in rabbits, that groups of rabbits or less sensitiveness might exist, and th unit dependent upon a fall of blood sugar even in a number of rabbits would not b constant. This has been borne out by ex



Rabbit.

FIG. 1.

and when the matter came up for consider an International Conference on Biological St it was agreed that the unit ought to be fixed, as possible, in terms of a stable standard pre of insulin, which is now in course of pro The work of preparing that sample was entr the National Institute for Medical Researcl

Insulin prepared by the methods abou described is stable, and it has been found t eparations which have been kept in hot clima period of six months give the same figures or as when originally prepared.

The preparation of insulin.

As has already been indicated, insulin is e from animal pancreas. The mammalian p exercises at least two diverse functions, nam secretion of insulin, which finally is utilise blood stream (endocrine), and the secretion of lytic enzymes, which find their way by the pa duct to the intestines (exocrine). Although th functions are performed by the same orga must be looked upon as quite separate. Ne

s, one can readily imagine that at some future ne there will emerge a clear reason why these two nctions are associated in the same gland. To the perimenter, and oven moro to the manufacturer, at association is the source of great difficulty, for e proteolytic enzymes of the pancreas rapidly use the destruction of insulin when present in the me fluid, and the problem of making insulin is gely that of saving it from destruction by this zyme action.

There is evidence that insulin is present in many, not most, of the body tissues, but there are strong asons for believing that it is mainly stored in certain ttered masses found in the pancreas of a tissue fering in structure from the rest of that organ, and own as the "Islets of Langerhans."

In many fishes the "islets" occur in separate es in close relationship with the gall bladder. e cod, for instance, there is a large principal which can readily be detached and so removed the sphero of action of proteolytic enzymes. ormick and Noble in Toronto, and Dudley in country, have obtained very high yields of insulin n this tissue, amounting to 20–30 times the amount ilable from mammalian tissue.

Dr. Dudley has kindly lent me the advance proof a paper which is about to be published, in which shows that as much as 40 clinical units of insulin r gram of islet tissue can be obtained. The diffi- lty of collecting such tissue for manufacturing rposes is very great, however, and each dissected h only yields a very small amount of islet tissue, refore this source of supply is not likely to prove ful on the large scale. Working on dogs, Best, ith, and Scott (J. Biol. Chem., **59**, xxx) have ntly prepared an active blood sugar-reducing nciple from brain, heart and skeletal muscle, od, lung, liver, spleen, kidney, submaxillary, roid and thymus glands.

From these results it appears possible that other l better raw material than ox, pig, and sheep creas may be found. For the present, however, the purpose of manufacture we are confining selves to the use of mammalian pancreas available n abattoirs.

Almost immediately after the death of the animal loss of insulin through proteolytic action begins, although during life the insulin remains in the sues apparently unaffected by the trypsinogen, n after death the latter becomes activated and islet tissuo becomes transfused by dissolved zymes. Their action may, however, be arrested: by the addition of alcohol of such a strength that enzyme is precipitated; (2) by bringing the nperature below zero; (3) by rendering the fluid re acid than p_H 3·5 by the addition of sulphuric hydrochloric acid.

The preparation of insulin comprises extraction and ubsequent purification. During the extraction and early stages of purification every advantage must be taken of these methods of delaying the rate at which its natural destruction proceeds. Once the destroying enzymes have been removed, the substance is stable if kept sterile. In outline the method of preparation consists of:—

(1) Procuring, dissecting, and cooling the pancreas glands as rapidly as possible after the death of the animal.
(2) Grinding or mincing at a low temperature to break up the cells very thoroughly.
(3) Rendering the material acid to p_H 2·5 or alkaline to p_H 7·0, in order to set free the insulin from the tissue on which it is adsorbed.
(4) Extracting it with alcohol of such a strength that but little of the enzyme is dissolved, and as much as possible of the insulin. For this purpose alcohol of 65–70 % strength has so far proved the best solvent.
(5) Clarifying this extract by cooling it to –5°, and filtering or centrifuging it.
(6) Concentrating at a low temperature to 1-10th of its volume, extracting the fat, and filtering.
(7) Precipitating the proteins with ammonium sulphate or with absolute alcohol at p_H 5.
(8) Precipitating the protein mixture successively with alcohol and picric acid, and finally by adjusting the aqueous solution to p_H 5·2. Proteins which are precipitated above and below p_H 5·2 do not merely dilute insulin, but are antagonistic to its action. This purification is consequently of great importance.

Insulin, when pure, may be almost completely precipitated at its iso-electric point, but the presence of accompanying proteins tends to keep it in solution, even at this point. The most useful reagent in effecting this purification is picric acid, used according to the method described by Dr. Dudley. By this means alone 90 % of the inactive protein may be removed from some samples of crude insulin.

Purification is thus effected by combining the use of precipitants such as picric acid and ammonium sulphate with iso-electric point precipitation.

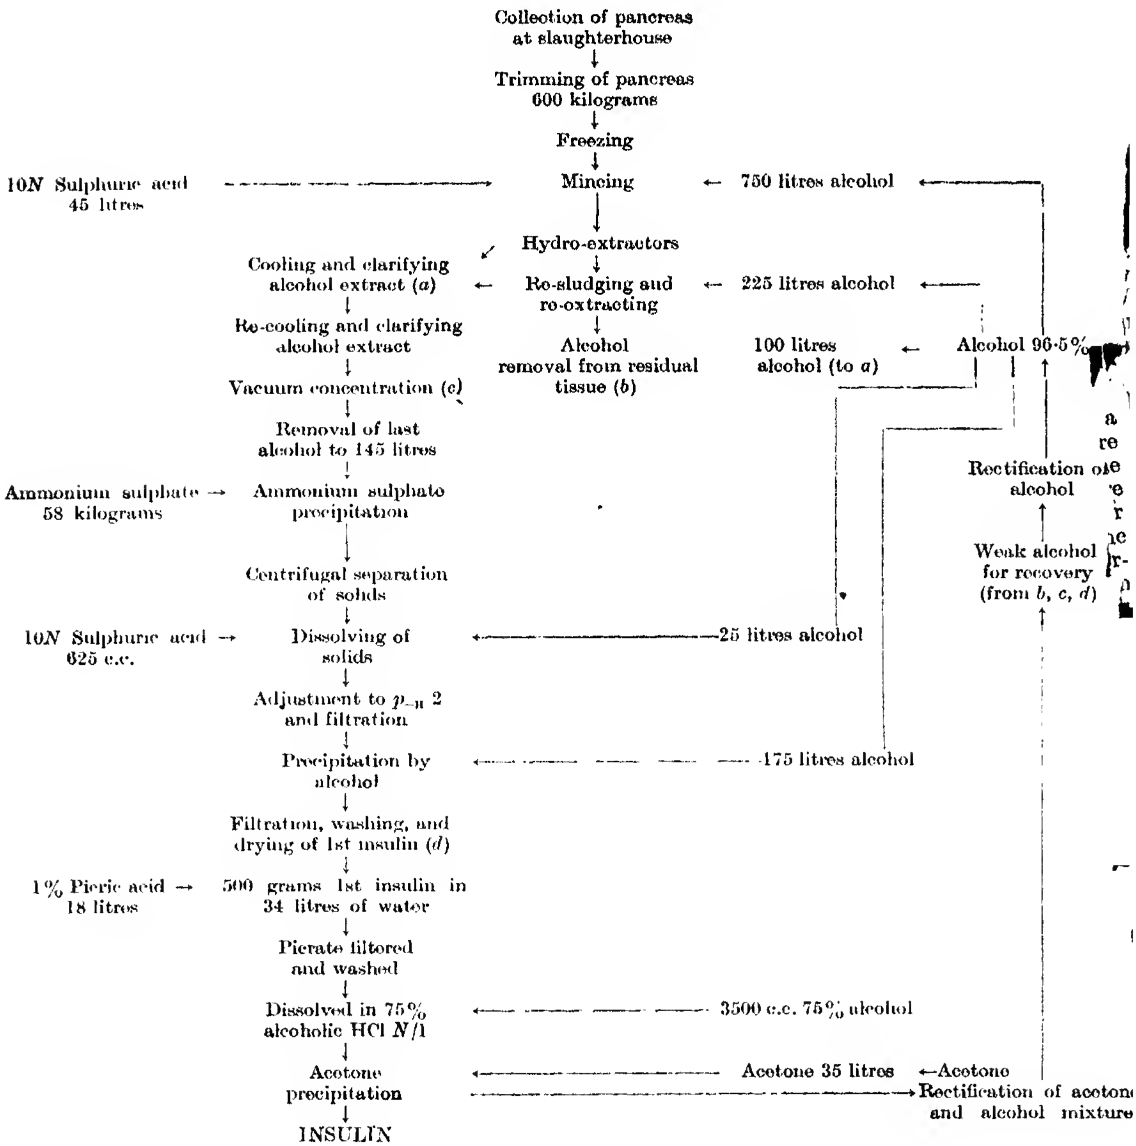
The laboratory method of preparing insulin has been published in detail by many workers. Particular attention may be drawn to the work of Banting, Best, Collip, and Macleod (Trans. Royal Soc. *Canada*, 1922, **16**, 1), Dudley (Biochem. J., 1923, **17**, 376), Dudley and Starling (Biochem. J., 1924, **18**, 147), Doisy, Somogyi, and Shaffer (J. Biol. Chem., 1923, **55**, xxxi; 1924, **60**, 31).

The principles of the method having been described, it will be best to deal at once with the process as interpreted on the large scale.

The large-scale manufacture has been installed as a continuous process. It can be followed by the help of the accompanying flow sheet. The plant has been so arranged as to ensure rapid handling, continuous recovery and strengthening of alcohol, automatic control of temperature, and so forth. Its chief interest lies in its arrangement, which cannot readily be described without the help of a larger number of photographs than can be reproduced in the *Journal*.

When sixteen months ago this manufacture was commenced, the yields obtained were very low, though quite as high as those obtained in other laboratories, being but 50 units perkg. of pancreas. There was also at first a great loss of alcohol. As our knowledge has

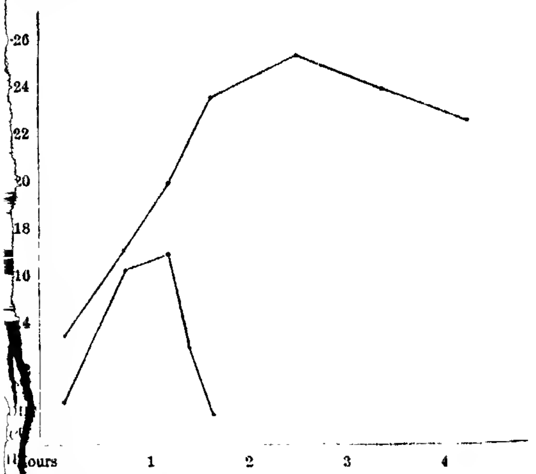
FLOW-SHEET OF INSULIN MANUFACTURE.



extended and the plant has been perfected, it has been possible to increase the yield twenty-fold, and to reduce the loss of alcohol to a very low figure. So great progress could not have been made without the assistance given by communications from many workers in the field, both in this country and in America and Denmark. In particular, mention must be made of the invaluable help given by the National Institute for Medical Research. As the result, within about a year the selling-price of insulin has been reduced by successive stages from 25s. to 2s. 8d. per bottle of ten doses, thus bringing the cost of treatment, at first prohibitive to many, within the reach of all. At the same time we have been able greatly to improve the purity of the insulin as it is issued for use.

The *rationale* of the present treatment of *diabetes mellitus* with insulin is founded upon the assumption that it is desirable to rest the islet tissue of the pancreas in order to re-establish its function. For this purpose, it is obviously desirable to get rid of the abnormal concentration of sugar in the blood for the sake of the general healthy condition of the body tissues. Accordingly, the dietary is adjusted to a low level and insulin is administered. The curves (Fig. 2) illustrate the effects of a large dose of sugar on a normal and on a diabetic individual. After 1½ hours the excess of sugar above 0·1%

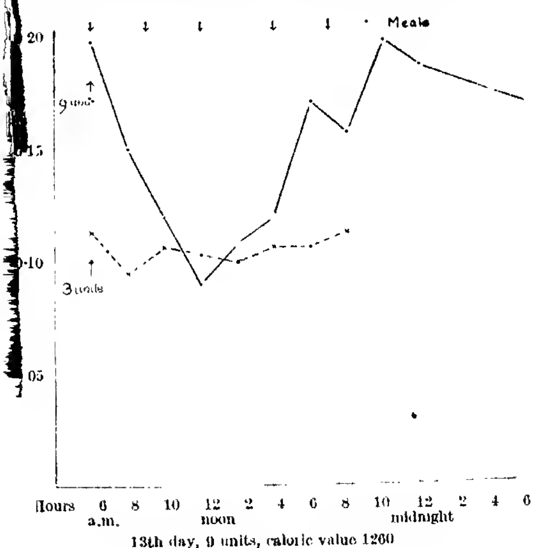
s disappeared from the blood of the normal individual; indeed, the natural supply of insulin has ought the blood sugar a little below normal, and little later the normal will be re-established by



showing diabetic (upper curve) as against normal (lower curve) after ingestion of 40 g. of glucose.

Fig. 2.

wing upon the glycogen stored in the liver. In diabetic, the case is far different, the sugar has en high above the level (0·19 to 0·20 %) at ich it escapes through the kidneys and otherwise,



13th day, 9 units, caloric value 1260
51st day, 3 „ „ „ 1620

Chart to illustrate fall of blood sugar—G. Graham.

Fig. 3.

the detriment of the general cell functions of the dy. Nor has it fallen to the initial figure even er four hours.

The next curve (Fig. 3) illustrates the effect of the ilful regulation of diet with insulin administration a case recorded by Dr. George Graham, and shows how a comparatively normal blood sugar may be maintained in this way. Note the increase of diet and decrease of insulin.

Dr. Graham's object here is to maintain the blood sugar very slightly above the normal, but well below the threshold of leakage. The reason for aiming at a level just above the normal is that the function of the islet cells is naturally stimulated if the blood sugar is 0·10 % or over, but depressed if it falls below this level, neither too much stimulation nor depression being regarded as desirable.

In a few words then, the basis is that in a normal individual insulin pours into the blood in such quantity and at such rate that the sugar content of the blood is well controlled. In a diabetic this is not the case, consequently at least a partial correction may be made by injecting insulin at intervals of several hours, the time of such injection being coordinated with the principal meals. Too much insulin produces effects which are no less serious than those resulting from a shortage; it follows, therefore, that it must be administered with great care. It is important to determine the sugar in the blood and urine at intervals, medical skill being, of course, necessary for the interpretation of the figures observed. Over-dosage with insulin produces serious symptoms demanding immediate treatment, or a fatal issue may result. These symptoms are quickly relieved if sugar or glucose is taken by the mouth. A common objection to the treatment is the inconvenience of submitting patients to frequent injections. These need generally to be given twice daily; it is not impossible, however, that there may be discovered an adjuvant substance to be administered with insulin, having the effect of spreading its action over a longer period of time. It is certain that some preparations of insulin act more quickly than others. When we have more knowledge as to the cause of this, it is to be hoped that it will be possible to supply an insulin which works quite satisfactorily if administered at much wider intervals of time.

Abundant evidence is at hand as to the wonderful results achieved by the treatment. I will content myself with two examples, the first being a case of coma to show the remarkable change in the blood content which accompanies these dramatic recoveries, the second that of a young diabetic to illustrate the wonderful improvement in general health which results from the treatment.

Very severe diabetics are likely to die in a state of coma. The onset of these symptoms had until recently been regarded as proof that death was at hand. With insulin treatment recovery from the comatose condition is not only likely, but probable; numerous cases are on record of people who have thus been snatched from the jaws of death and have been able a few weeks later to return to their homes and daily avocations.

The curves (Fig. 4), show the rapid fall of both sugar and acetone, as well as the increase of carbon dioxide in the blood as the patient was resuscitated.

For the record of my second example I am indebted to Drs. Passmore, Raven, and Poynton, and to the *Lancet*. A child who had been under medical

matters at the present time, the year of the Great Exhibition. Dr. Armstrong had also been the originator of the idea of the extraordinarily able pamphlets, published by the Society, which were being sold at Wembley, and which gave in a popular form to the public a greater knowledge of what the chemists of this country really are than perhaps anything else that could have been done.

During the two years of Dr Armstrong's presidency they had admired at all times the courage he had shown in leading them and in increasing the prestige of this Society. They were very grateful for the amount of time he had sacrificed, for the amount of detail work which he had done at great personal inconvenience, and yet it had been that very detail work which had brought the Society to the high pitch of efficiency and to the best Annual Meeting they had ever had. On behalf of all the members of the Society, without exception, he assured Dr. Armstrong that they were deeply grateful to him and hoped for his continued interest in the progress of the Society.

DR. E. FRANKLAND ARMSTRONG, in acknowledging the vote of thanks, suggested that their thanks were really due to the Local Committee for organising the meeting, and he moved that their best thanks be given to the Local Committee.

MR EDWIN THOMPSON, on behalf of the Liverpool Section, thanked the President for his kind remarks. He thought the meeting had been a success, and it had only achieved that success because of the kind offers of hospitality they had had and the papers that had been presented. Their thanks were due to all who had contributed to the success of the Meeting, and to the University for allowing them the use of its buildings. He hoped the success of the Meeting would be the means of bringing into closer co-operation the University of Liverpool and the Liverpool Section of the Society of Chemical Industry. He also paid tribute to the large amount of efficient work which had been done by the Local Secretary, Mr. Gabriel Jones.

The business then concluded.

The Lecture given by Prince Ginori Conti on "The Larderello Natural Steam Power Plant" will be reported in *Chemistry and Industry*.

Lord Leverhulme's "Messel Memorial Lecture" will appear in a later issue of the *Transactions*.

THE INFLUENCE OF STORAGE AND OF EMULSIFICATION ON THE VITAMIN A IN COD LIVER OIL.

BY J. C. DRUMMOND D.SC., F.I.C., S. S. ZILVA, D.SC., PH.D., F.I.C. AND KATHARINE HOPE COWARD, D.SC.*

The ease with which vitamin A is oxidised even at ordinary temperatures has been observed so often by the authors that it seemed desirable to investigate various samples of cod liver oil with a view to determine to what extent this dietary factor may be destroyed under the ordinary conditions of storage of such oils, and how far it might be destroyed in the process of emulsification to which the oil is often subjected.

Storage of oils.

A number of oils of which the activity had been determined in the summer of 1921 were again tested in the winter months of 1922-23; in order to avoid any error which might be due to a difference in response in the animals in winter and summer months, the oils were again tested in the summer of 1923. Most of the samples were contained in ordinary glass bottles of about 1 litre capacity. In most cases they were little more than half full of oil, and during storage, which had for part of the time been on an open shelf in the laboratory, and for the rest in a dark cupboard, appreciable oxidative changes had taken place, as indicated by the formation of a sticky resinous material at the surface of the oil. The extent to which these changes had affected the composition of the oils themselves can be gauged from the analyses of the samples, which show a marked fall in the iodine values from a normal figure of about 178 to values around 150, and a rise of acid value from less than 2 to 5 and over. The results of testing for vitamin activity are tabulated below.

Oil.	Dosage required for normal growth. July-Aug., 1921.	Jan., 1923.	Sept.-Oct., 1923.
1. Unfiltered Lofoten oil	0·003 g.	0·04 g.	0·02–0·04 g.
2. Unfiltered Kjelvik oil	0·006	0·01	0·04
3. Filtered oil, first fraction Lofoten	0·02	>0·02	>0·04
4. Posetran, Lofoten oil	0·003	0·04	0·02*
5. Coal-fish liver oil	0·003	>0·08	>0·08

* This was the only case observed where the dosage required in the summer was less than that required in the previous winter, and it may possibly be accounted for by the fact that the rats used for the winter test had had a longer preparatory period on the deficient diet than had those used in the summer test.

It is apparent, therefore, that storage of cod liver oils under conditions permitting oxidative changes will tend to reduce the nutritive value of the oils. On the other hand, our previous experience has taught us that when oils are stored so as to reduce to a minimum the contact with air, as by filling the bottle almost to the top with oil and tightly stoppering, they may preserve their vitamin potency unimpaired for at least two years.

Several cases in which a practical application of these observations has been of value have come to our notice. One interesting case was noted by our colleague, Capt. J. Golding, D.S.O., in which a farmer failed to observe any benefit from the administration of cod liver oil to his stock of pigs. The oil was examined by us and found to be an old sample of "cattle" cod liver oil which had been considerably oxidised, and which had lost all detectable traces of vitamin activity.

Cod liver oil emulsions.

The desire to overcome the difficulties of administering cod liver oil alone has led to the introduction of numerous devices for masking its unpalatable nature and to the widespread employment of pre

* Beit Memorial Research Fellow.

arations which can be roughly divided into (a) simple " emulsions, in which the oil is the chief utritive component, and (b) " complex " emulsions, hich contain other foodstuffs such as malt extracts.

(a) *Simple cod liver oil emulsions.*—Preparations f this type are placed on the market in this country y a number of firms. The majority are carefully ade from materials of good quality and actually ontain the amount of oil claimed. The emulsifying gent is usually a gum, and glycerol is in some cases dded. By the kindness of the directors we have een permitted to inspect the processes by which ertain commercial cod liver oil emulsions are made.

The actual process of emulsification employed iffers in detail in different factories, and in most, not all cases, involves considerable admixture of he oil in a fine state of division with air, although e temperature is usually kept low. At first sight, erefore, it appeared probable that the vitamin A lue of the oil would be appreciably diminished by e process of emulsification. Furthermore, certain rieties of gums employed for the purpose of making he emulsions give well-marked reactions for " oxidses," the presence of which might be likely to accelrate the loss of vitamin by oxidation. In order to ain definite information on this point a sample of cod ver oil of ascertained potency was selected from our tock and made into emulsions in the dispensary of niversity College Hospital by Mr. Hampshire, to hom we owe our thanks for his kind help. Emulions containing rather under half their weight of od liver oil were made under similar conditions ith: (1) gum acacia; (2) gum tragacanth, and 3) Irish moss (carageen). Samples of the fresh mulsions were tested immediately after preparation, hilst other portions were stored in filled, welltoppered bottles and either exposed to light n an open shelf, or kept in a darkened cupboard. he stored samples were tested at the end of nine nonths. The results are given below.

Daily dose required to give growth in experimental at of about 100 g.:

1 Original oil, 0·02 g.

2. Emulsion 50% oil should therefore be 0·04 g. f no destruction occurs. Dosage found:—

Agent	Original emulsion.	Emul. kept in dark.	Emul. kept in light
1 Irish moss	0·08g.	0·08g.	>0·8g.
2 Acacia	1·0	—	
3 Tragacanth	0·04	0·01	No activity

These figures show clearly that the emulsification ith Irish moss caused approximately a 50% reducion in the vitamin value of the oil. No further fall ccurred as a result of nine months' storage in the lark, but a slight decrease was noted in the sample xposed to the light. In the case of the acacia mulsion serious inactivation occurred, and so much mulsion was used in this test that none remained to est after storage. The initial drop is, however, so big that a small additional decrease would be of little onsequence. The tragacanth emulsion showed no ppreciable loss of vitamin activity except after storage for several months exposed to the light. The cause of this has not yet been made clear. It is interesting to compare the degree of initial destruction on emulsification with the response given by the emulsifying media for the presence of " oxidases ":—

	Loss of vitamin A on emulsification.	" Oxidase " reaction
Irish moss	++	+++
Acacia	+++	++
Tragacanth	—	—

Certain commercial emulsions contain tragacanth as an emulsifying agent, so that if " oxidases " do play any part in reducing the potency of emulsions of cod liver oil, the employment of this gum is a factor for safety. Others contain acacia or a mixture of acacia and tragacanth. Apart from this, however, the grinding of gums prior to their use in the commercial manufacture of emulsions frequently generates so much heat that the "oxidases," if present, must be, to a large extent, destroyed.

Another series of tests were made on a sample of cod liver oil before and after it had been made into a commercial emulsion. The results in this case indicated little appreciable loss of potency.

Two other well-known commercial brands of cod liver oil emulsion were carefully examined by us with the following results:—

Sample.	% of oil by weight found.*	Vitamin dosage in grams. Fresh emulsion	After storage for 9 months in dark	in light
A	39·4	0·04	0·04	0·04
B	35·5	0·04	0·04	0·04

* Determinations of oil in such emulsions present some difficulties. These figures show that the emulsions are probably built up on a 40% formula of the type indicated above.

These results indicate that storage of such emulsions, whether in light or dark, does not appreciably affect the vitamin value of these products, provided that they are kept from contact with air in filled and well-stoppered bottles. Furthermore, although no tests of the vitamin A value of the oils used in making such emulsions were actually made in these two cases, it would appear safe to assume from our own experiments on tragacanth emulsions that no serious loss of vitamin occurs during their manufacture. This view is supported by the fact that such preparations are practically always made from high-grade Norwegian liver oils obtained from the Lofoten area. From our wide experience of these oils we can give their approximate vitamin value in terms of " dosage-in-grams required to give growth in a 100 g. rat " as 20 mg. Assuming no destruction in preparation of a 40% emulsion, therefore, the vitamin value of such preparations would be about 0·05 g., a figure much of the order actually found.

(b) " *Complex* " *emulsions.*—Under this title are included a variety of products, chief of which are the malt and cod liver oil emulsions. Generally speaking, we have found these preparations, of which we examined six different kinds, to possess a vitamin value roughly proportional to the amount of oil they contain. This is an indication that the methods of commercial preparation cause little loss of physiological potency. Furthermore, with one exception, they were found to preserve their activity under the same storage conditions that are described above. It must be remembered, however, that practically all these preparations contain less oil than the " simple " emulsions, and that some of them may

contain as little as 15%. This fact should be borne in mind when these products are being considered from a vitamin standpoint.

Summary.

1. Cod liver oil may lose a considerable proportion of its original vitamin A value in storage under conditions that permit oxidative changes.

2. Emulsification of the oil with emulsifying agents, such as gums, may, in certain cases, cause a loss of vitamin activity. There is some evidence that such loss is less a consequence of the admixture with air than of the presence of oxidising agencies ("oxidases") in the gums used.

3. An examination of certain commercial preparations of cod liver oil emulsions indicated that little or no loss of vitamin A occurs during emulsification.

4. No appreciable loss of vitamin A value occurs on storage of such emulsions for periods of nine months, provided opportunity for oxidation is prevented.

5. More complex cod liver oil preparations, such as malt and cod liver oil products, appear to contain vitamin A, roughly speaking, in proportion to the amount of oil they contain. The processes by which the well-known brands are made would appear to have little deleterious action on the vitamin A.

6. Since oxidation is the chief factor concerned in the inactivation of vitamin A, it is obvious that storage of cod liver oil, and of products containing that oil, should, as far as possible, be effected with minimum exposure to air, at as low a temperature as possible, and in the dark.

The thanks of the authors are due to the Medical Research Council for a grant from which the expenses of this research were defrayed.

NOTE ON THE ACCELERATING INFLUENCE OF AN AZO DYE IN VULCANISATION.

BY T. J. DRAKELEY, A. ZEITLIN, AND L. H. WILLIAMS

Azo dyes are being introduced for the colouring of rubber, and in view of the fact that these are prepared by the coupling together of organic compounds, many of which are powerful accelerators of vulcanisation, it seemed desirable to determine whether a typical dye of this class would influence the process.

It may be noted that the colour bases of basic dyes, in common with most basic materials, possess accelerating properties. But, with very few exceptions, the principal azo dyes are not basic, hence no *a priori* conclusion can be drawn as to their accelerating properties.

The rubber used in the investigation was selected from the same batch of standard thin pale crêpe, and all the samples were vulcanised in a steam-heated "daylight" press at a pressure of 50 lb. to the sq. in. (147°). The dye employed was that obtained by coupling diazotised 2-naphthylamine-1-sulphonic acid with β-naphthol; it was insoluble in water, and free from mineral matter. The effect of the introduction of about $2\frac{1}{2}$ to 5% of the dye on the vulcanisation of the mixes given below was determined.

(*A*) *Pure rubber-sulphur mix.*—The following mixes were prepared: A.1, rubber 90, sulphur 10; A.2, rubber 87·75, sulphur 9·75, dye 2·5; A.3, rubber 85·5, sulphur 9·5, dye 5·0. Twenty-four hours were allowed to elapse between the mixing operation and the vulcanisation. The latter was conducted in ring moulds, which were introduced into a heated press with hot plates so that no rise was given. To ensure that the results should be strictly comparable, three samples, one from each batch, were vulcanised together. Five days after the vulcanisation, ring test pieces were cut, and were tested on the Schopper machine. From the stress-strain curves the following values for the extension were determined.

TABLE I.

Extension per cent. at a load of 600 g. per sq. mm.

Cure	A.1.	A.2.	A.3.
60 minutes	1205	1145	1090
90 ,,	1060	1025	990
120 ,,	940	925	905
135 ,,	904	890	875
150 ,,	874	865	853

The above results are plotted in Fig. 1, which shows that the extension for a fixed load decreased Fig. 1 from A.1 to A 3. That we are dealing with an

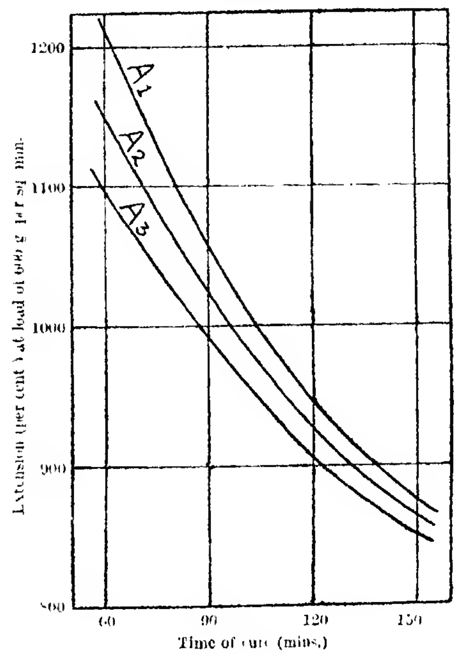

FIG. 1.

acceleration as opposed to a merely reinforcing action of the dye is confirmed by the determination of the vulcanisation coefficient. For instance, the following

ɛ the coefficients of vulcanisation for the 120 min- ɛs' cure, after correction for the sulphur present in ɛ dye: A.1, 3·52; A.2, 3·73; A.3, 3·89.

(B) *Rubber mix containing a small quantity of zinc ide.*—The mixes B.1, B.2 and B.3 were similar to 1, A.2, and A.3, respectively, but contained an dition of 2·5 parts of zinc oxide. The experi- ental observations were made as described eviously, and the following table gives the tensions:—

TABLE II.

Extension per cent. at a load of 600 g. per sq. mm.

Cure.	B.1.	B.2.	B.3.
60 minutes	970	930	890
90 ,,	860	840	820
120 ,,	795	770	760
135 ,,	770	750	735

On plotting these values, a diagram similar to g. 1 is obtained. It is apparent that the zinc ide has not markedly activated the accelerating operties of the dye.

(C) *Heavily-filled mix.*—In order to test the influ- ce of the dye on the curing of a heavily-filled mix, e mixes detailed in Table III. were made.

TABLE III.

	C.1.	C.2.	C.3.
Pale crêpe	140	140	140
Sulphur	15	15	15
Zinc oxide	20	20	20
Barytes	30	30	30
Whiting	30	30	30
Dye	—	5	10

The cured samples were tested in the manner eviously described, when the results given in able IV. were obtained.

TABLE IV.

Extension per cent. at a load of 600 g. per sq. mm.

Cure	C.1.	C.2.	C.3.
60 minutes	940	924	924
90 ,,	850	835	820
120 ,,	805	790	775
150 ,,	760	750	740

On plotting the values in Table IV., diagrams milar to those in Fig. 1 are obtained. It will observed that the accelerating influence of the ye has been reduced by the fillers, but is still ob- rvable. The decrease may possibly be due to the bsorption of dye by the fillers, or to the enclosing of e dye by particles of fillers.

(D) *Influence of the dye on the vulcanisation of an celerated cure.*—To determine the effect of the ye on an accelerated cure, the following mixes ere made: D.1, rubber 200, sulphur 4, zinc oxide 5, iphenylguanidine 3; D.2, same, with dye 5; D.3, me as D.1, but with dye 10. Samples of each batch ere cured for 25, 30, and 40 minutes, and rings were sted on the Schopper machine. The corresponding urves for each batch were found to be coincident, us indicating that the powerful accelerating ıfluence of the diphenylguanidine had masked the maller effect of the dye.

From the foregoing investigation, it would appear at the dye employed acts as a very feeble accelerator in non-accelerated mixes. It has been impossible to determine whether the dye itself causes the accelera- tion. It may be that (at the temperature of the vulcanisation) a trace of the dye suffers slight de- composition accompanied by the production of a degradation product possessing the observed acceler- ating properties. The effect, however, is so small that in ordinary practice it may be entirely ignored. In accelerated cures, the influence of the dye is totally inappreciable.

The thanks of the authors are due to the British Dyestuffs Corporation for providing supplies of the dye and diphenylguanidine.

DETECTION OF PERSULPHATE IN FLOUR, AND A RECENT BLEACHING AGENT FOR FLOUR.*

BY JAMES MILLER, F.I.C.

Probably the most common agent used for bleaching flour is oxides of nitrogen—"electric gas". this is readily detected by the well-known colour reaction with naphthylamine hydrochloride and sulphanilic acid. Potassium or ammonium persulphate probably comes next in importance, the persulphate being usually detected by means of a solution of benzidine in alcohol.

In view of the readiness with which per-salts liberate iodine from potassium iodide solution, it seems surprising that use has not been made of this reaction for the detection of persulphate in flour.

If a few grams of a flour containing persulphate be gathered on a microscope slide, then flattened and gradually immersed in a 10% solution of potassium iodide for about 10 seconds, withdrawn and allowed to stand, the particles of persulphate begin to show up as brown spots within one minute, owing to the liberation of iodine: half an ounce of persulphate per sack of flour can be readily detected in this way.

Another bleaching agent for flour has been recently introduced under the name of "Novadelox-B." This seems to consist of a mixture of benzoyl peroxide, acid calcium phosphate, and tricalcium phosphate, and its bleaching action is, no doubt, attributable to the benzoyl peroxide. The properties of this sub- stance have been described by Farmer (J., 1921, 84 T). It is stated to be a powerful antiseptic, and has been used for the treatment of burns and ulcers: its internal use has been abandoned on account of its poisonous action on the blood.

* Read at a meeting of the Manchester Section on May 2, 1924.

The crude product melts with decomposition at about 98° ; the pure compound melts at 103°—104°. Gradual decomposition commences at a temperature much below the melting point, and as it proceeds the reaction accelerates to such an extent that in a warm place explosion may result. Mixing with inert material renders the substance more stable, and this may be one reason for the presence of calcium phosphate in the mixture under consideration.

If a little benzoyl peroxide be added to potassium iodide and starch solution, no immediate colour is produced, but on shaking and allowing to stand, iodine is slowly liberated and a blue colour gradually develops ; this reaction takes place at once if the mixture be boiled and cooled.

For the detection of benzoyl peroxide in flour, the same reagent is used as for the detection of persulphate, viz., a 10% solution of potassium iodide, but as the reaction takes place very slowly in the cold, it is necessary to use heat.

About 5 g. of the flour contained in a porcelain dish are mixed into a paste with the reagent, the paste is spread over the dish and heated on a boiling waterbath for five minutes. After cooling, the presence of benzoyl peroxide is revealed by dark spots on the under-side of the cake ; half an ounce per sack is readily detected.

Benzoyl peroxide can be detected in a flour containing both benzoyl peroxide and persulphate, by extracting the latter with water and applying the above test to the residue after draining on filter paper.

The benzidine test, applied as described above for persulphate, gives with a flour containing benzoyl peroxide, on standing for about 15 min., dark spots which to the unpractised eye might be confused with those given by persulphate.

A mixture of benzoyl peroxide and flour in the proportion of half an ounce per sack gave the potassium iodide reaction with undiminished intensity after standing for 15 weeks.

Since reading the above, loaves have been made from flour containing ½ oz. and ¾ oz. of benzoyl peroxide per sack respectively. The crumb of the loaves was examined by the potassium iodide test and the reaction for benzoyl peroxide was obtained in both cases, indicating that the whole of the peroxide had not been decomposed during the baking process.

The crumb of a loaf made from flour containing ¾ oz. of "Novadelox-B" gave a negative result for benzoyl peroxide.

NOTE ON THE BLEACHING ACTION OF HYPOCHLOROUS ACID.

BY S. R. TROTMAN.

Some time ago a criticism was published by Mr. R. L. Taylor (J., 1923, 79T) of some statements made by me with regard to the bleaching action of hypochlorous acid. Taylor maintained that my results were explained by the fact that hypochlorous acid, prepared by passing chlorine into water containing chalk in suspension, always contained calcium hypochlorite. In his paper entitled "Notes on hypochlorous acid and chlorine, with comparisons of their bleaching action" (J. Soc. Dyers and Col. 1922, 96), Taylor states that "to enable either chlorine, or hypochlorous acid, to bleach linen some hypochlorite must be present as well, and it is evident that by the addition of calcium carbonate to either chlorine water or hypochlorous acid the requisite amount of hypochlorite is produced." In a footnote, it is stated that if hypochlorous acid is shaken with calcium carbonate the filtered solution subsequently gives a precipitate with ammonium oxalate. This is all the evidence I can find for Taylor's insistence on the fact that the bleaching action of hypochlorous acid is due to the presence of hypochlorites. I do not think that the statement is warranted by Taylor's own experiments.

When Taylor speaks of hypochlorous acid he means presumably, that prepared by his method of distilling a mixture of bleaching powder and boric acid. I have prepared many lots of the acid in this manner, distilling both under ordinary and reduced pressures. I find that the distillate always has a p_H value of about 4, that it invariably has a slight odour of chlorine, and that the presence of free chlorine is confirmed by Taylor's arsenious acid method of titration. That is, I am of opinion that Taylor's hypochlorous acid contains traces of free hydrochloric acid and chlorine.

Naturally, when this acid is shaken with powdered calcium carbonate, some calcium is dissolved. If the mixture is filtered the p_H of the filtrate is about 6·0. If this filtrate is kept carefully, its p_H remains constant for a long time, and the acid does not dissolve any more calcium when shaken with calcium carbonate. But if the filtrate is kept in a warm room or exposed to a strong light a p_H of 4 is again apparent. The acid then dissolves more calcium.

If hypochlorous acid is prepared by the action of chlorine on water containing suspended chalk, the filtrate has a p_H of about 6 and does not dissolve calcium when shaken with chalk, as long as it is kept under suitable conditions. In one experiment hypochlorous acid made in this way was kept in contact with chalk for 24 days. The dissolved calcium was exactly the same at the end as at the beginning of the experiment.

JOURNAL of THE SOCIETY OF CHEMICAL INDUSTRY

ol. XLIII., No. 30.] TRANSACTIONS [JULY 25, 1924.

Annual General Meeting

Liverpool, July 10th, 1924,

(Continued from p. 236 T.)

The President in presenting the Messel Medal poke as follows:

The Messel Medal, founded in memory of Dr. Rudolf lessel, is conferred this year on Viscount Leverhulme. r. Messel was an example of that rare combination f a chemist, a chemical engineer and a man of usiness—a pioneer of our industry; he invented a ew process and brought it and the industry conected with his process, the manufacture of sulphuric cid, to a technical and commercial success. In lecting Lord Leverhulme to receive the Medal your ouncil wishes to pay tribute to him as the founder f one of our greatest chemical firms, as the leader f one of the most important industries based on hemical science, and above all, as a leader of men nd an Empire builder in the very widest sense of he term. Lord Leverhulme's career is so familiar o us all that I need not describe it to-day; you now him to be a man of inexhaustible energy, ibrating with ideas and possessed of the highest eals. he might be described, if one may coin the hrase, as the greatest door opener in British ndustry. No one can have made more opportunities or the individual young men of his staff to grasp r done more for the technical and material progress f industry. Himself primarily a salesman, he can n turn act as financier, architect, technical chemist nd what not else, not neglecting the love and atronage of art, and his technical knowledge in ach profession is such as to qualify him beyond oubt as a full member of the professional Institute.

Industry, let us say chemical industry, cannot ive by the brains of chemists alone; their products ust be financed and sold, the factories in which hey work must be planned and built with due egard to the economic geography of their situation, onsidering always the raw materials which must be roduced and brought to the works. The wares ust be presented in an attractive form and made nown to the public. In every one of the provinces f activity I have mentioned, Lord Leverhulme has ound his *metier*, and so in the briefest number of ears has built up an organisation which is world ide, both in fact and in fame. He has that long xperience that doth attain to something like rophetic strain, and his prophetic vision and his ireless energy have often made him most successful hen the difficulties appeared greatest.

Lord Leverhulme has built up a technical industry, uilt it first by dint of his own personal effort and is own hard work, and secondly by his encouragement and application of every form of science, our own science of chemistry above all. He will permit me to recall one name to-day, that of a chemist who stood close beside him as his right hand man for many years, a former President of our Society, Mr. John Gray. We have often heard Mr. Gray relate how quick was Lord Leverhulme's insight into the technical problems which daily confronted them in early days at Port Sunlight, and how unerring was his judgment in choosing the right course. Those of us who work with him to-day know that time has made no change in this power of going to the heart of things, and that no expenditure of time or money on technical progress or investigation is stinted when a good case for it has been established.

Lord Leverhulme has not confined his attention to the financial, commercial or technical sides of the great undertakings he controls. He has not forgotten the human element; he has realised, as every wise man in time realises, that getting and spending are not the only duties of mankind. He has for many years taken a great interest in the happiness and the health of those who spend their lives in the industry. Port Sunlight is well known as a splendid example to all those who control important works; Lord Leverhulme has also taken a prominent part in profit-sharing schemes, in the organisation of industrial hygiene and in a variety of other efforts to enable those who are employed by his companies to attain to a high standard of life, including in this phrase not only comfortable and healthy homes but some appreciation of art and literature and that moral and ethical conduct without which business is merely sordid.

In the year 1891 the application of William Lever was approved by the Council for election to our Society. To-day its list of members bears no name more respected, more honoured by us, or more fitted to receive the Messel Medal than that of Viscount Leverhulme.

The President then handed the Medal to Lord Leverhulme.

Lord Leverhulme said: I was simply overwhelmed when I received your invitation to become the recipient of the Messel Medal this year, and I need not tell you how great a pleasure it is to me to be with you to-day and to meet not only scientists, but scientific business men. I am very much like an amateur musician, I think; the amateur musician is always considered by his musical friends to be a business man, and by the business men to be a musician. Similarly I do not quite know where I am on science and business.

D

SECOND MESSEL MEMORIAL LECTURE.

Science, Religion, and Workshop.

By THE RT. HON. THE VISCOUNT LEVERHULME, LL.D.

Delivered at the Forty-third Annual Meeting of the Society at Liverpool, July 10, 1924.

When I was honoured with the invitation to be with you here to-day to receive the Messel Medal and to deliver the Messel Lecture for 1924, I felt very much inclined to shirk the responsibility on the ground that my knowledge of chemistry is confined to some evening class instruction I took in chemistry, under the guidance of a teacher, some fifty-seven years ago in Bolton. The effect of those lectures was to convince me of the truth of what the poet Pope wrote :—

"A little learning is a dangerous thing ;
Drink deep, or taste not the Pierian spring."

At the time, namely 1867, I was a grocer's apprentice, and could attend the chemistry class but one night a week, another night being devoted to shorthand, another night to taking lessons in drawing, and a fourth night each week to instruction in French. I am sure you will all agree that this was not even tasting the Pierian spring, let alone drinking in the shallowest sense. But if I did not acquire more than a smattering of chemical knowledge, I acquired a profound veneration for the work of the chemist, and when, many years later, I became a soap maker, I resolved, and have acted upon that resolution ever since, to surround myself with the skill of the chemist in solving all the problems of the manufacturer, and to endeavour to break through the old "rule of thumb" methods that prevailed in the soap industry.

You will see, therefore, that my first impulse, on receiving this generous mark of your confidence in me, was to explain my inability, but the invitation contained such a delicate compliment that it would have been churlish and ungracious on my part to have refused. I was very much like the gentleman who, in the old days of the hansom cab, on arriving home with no money less than a £5 note in his pocket which the cabman was unable to change, was pleased to observe, in his dilemma, a gentleman approaching. Raising his hat, he explained very politely to the stranger the difficulty he was in and asked him if he could change the £5 note? The gentleman, no less courteously, raised his hat and replied that he was sorry he could not do so but that he thanked him for the compliment.

I am not proposing to weary you with the fables woven around the art of the soap makers of Phœnician days, nor the discovery of soapworks among the ruins of Pompeii, nor of classic stories of Nausicaa and her maidens.

The invention of the art of soap making is shrouded in the mists of antiquity, but the science, as distinct from the art, of soapmaking is less than a century old.

I am content to believe for a certainty that by the time the cave man arrived and homes were formed in caves then would come spring cleanings, and if the cave woman was not able to seek the aid of soap, that to maintain household cleanliness was a pretty hopeless task imposed upon her. As long as home was amongst leafy glades of forests, and man's bed the bough of some tree rendered safe sleeping quarters by a strong grip maintained by prehensile tail, then soap was a negligible quantity in the economy of the family home. With every advance in the home comforts of life from the cave to the cottage and palace, there came an ever-increasing demand for soap and all saponaceous compounds. And the olive tree, coconut tree, palm oil tree, and the fat of animals were requisitioned to supply the demands of the soap maker's art.

It is disconcerting to our insular pride and love of first place priority in all developments to learn that it was not until some six centuries ago that soap was first introduced into the daily life of the people of the British Isles.

No doubt the proud, haughty Roman conquerors had brought soap into Britain with their Roman legions, but its use would be confined to Roman patricians, governors, generals, and their wives and daughters. We of British stock were not finding it easy to provide even coarse food and scanty clothing and had no opportunity to supply ourselves with the eleganceies and comforts of life. Perhaps this accounts for the natural instinctive abhorrence and repugnance to soap of the British small boy. And is there not the story of the "rough diamond" labourer who had met with a serious accident to his head, which necessitated an operation at the hospital, whose hair on his scalp was so matted with dirt that the surgeon was constrained to enquire, "Do you never wash your head, my good fellow?" and the good fellow replied, "Naw, I'd as soon think of washing my feet as my head."

However, once soap was introduced, its virtues for cleanliness personal and domestic were speedily recognised, and it is estimated that to-day the consumption of soap in Great Britain, per head of the people, is as high as or higher than that of any other people or country in the world.

This present-day British love of soap has been in evidence only for some half-century or so, but soap must have been more or less in daily use in France for over a century prior to coming into its own in Great Britain, for in 1793 the insurgent women of Paris, as stated in Carlyle's "French Revolution," made their plaintive battle cry "Du pain et du savon." It is largely due to the research

chemists of the United Kingdom that the conversion of the art of soap making into the science of soap making during the last century has been achieved. Not that British chemists have been the pioneer explorers or sole discoverers in the search for a scientific basis for the soap maker's art. But British soap makers have led the world in seizing upon those improved methods which the science of chemistry has placed at their disposal, in their service of the public. And to-day British soap at home and overseas enjoys the entry into the markets of the world, as being higher in quality and lower in price than the soap produced by any other nation, and this reputation has been honourably and laboriously won by hard work and persistent effort.

So now we find in the twentieth century of the Christian era the art and science of the soap maker in ideal combination, an important element in the life of civilised peoples.

It has been often stated that cleanliness is "next to godliness," and, notwithstanding the retort of the housewives living in the manufacturing towns of Lancashire and Staffordshire that in their town it was "next to impossible," there is sound logic under the statement that cleanliness is really and truly "next to godliness."

But this truism brings us to consider whether science or religion has accomplished most for the progress and civilisation of mankind.

Don't let me create any wrong impression as to whatever views I may hold on the relativity—I think that is the modern expression—of science and religion. Each has its right and proper place in the real permanent happiness, well-being, civilisation, and progress of the world, but our English language so easily lends itself to loose methods of thinking, apart from our British way of muddling together, in a kind of "scrambled egg" manner, totally dissimilar truths, that clear thinking on the relative ...ions of science and religion are necessary and ... more needed than to-day.

...ience and religion cannot be made into scrambled ... in the economy of life. Religion is not in ...ict with science, nor is science in conflict with ...on. Religion must ever be the compass and ... through life's voyage with its storms and ...ns.

...t for some eighteen centuries the Bible has been ...l by professors of religion upon mankind, not ... as a guide setting forth the Sermon on the ...t, the principle of the Golden Rule and the ...en Commandments as codes and rules given us by religion to guide us through life in our social relationship to each other; but also that the Bible's Eastern fables and illustrations, coloured with the graphic imagery and poetry of Eastern peoples, must be accepted as scientific truths that could never be challenged without bringing down with them religion, with its codes and guides for moral conduct, in devastating ruin.

As we know, the Christian Church burnt at the stake ... Italian philosopher, Giordano Bruno, or tortured ... threatened to torture with rack and thumbscrew ...e pioneers of science and truth, such as Galileo and others, who had the courage to wish to separate the chaff of impossible claims to scientific guidance from the real wholesome grain of the moral truth and indisputable reality of the ethical essentials of life given us in the Bible. It has been this bigoted attitude of the Church through at least sixteen centuries of the Christian era, that is to say, from the second to the eighteenth century, that has produced a disastrously sterilising effect on the benefits science would have lavished with generous hand on mankind. It has been science, in spite of all persecution arising out of mistaken interpretation of the teachings of the Bible, that has been the vitalising power in raising the condition of mankind to its present altitude, and it is to science we must look for still greater advances and still higher levels of comforts and elegancies of life the future should have in store for mankind.

Science and men of science, once freed from the thraldom of the Church's wrong interpretation and maladministration of the Bible, have made more progress in the raising of the level of comfort and happiness of mankind in the last two centuries than was achieved in all the preceding centuries of the world's history.

Professors of religion and professors of science must learn to go arm in arm together through life to raise and elevate mankind higher and higher above the brute beast and nearer and nearer to the angels.

In the past centuries Europe has seen nations enfeebled almost to the point of collapse by excess of religious zeal and blind separation from the scientific truth of what, for want of a better word, we have named "nature." And to-day some countries of Europe, most notably Russia, are enfeebled to the point of collapse by scorn and contempt for religion, dispersal and murder of its advocates, and by denial of God Himself. It has been truly said that whoever denies God has to face the difficulty of explaining the existence of mankind.

Religion, it is said, languishes from lack of new problems to solve in life, but professors of religion and searchers after real solid basic truths of religion and the Bible are finding each day fresh ethical problems requiring solution for the moral and social life of mankind, and betterment of the human race.

It is true that to follow the teachings of the Bible intelligently and faithfully requires no new discovery or guidance, but with each development and progress of mankind clearer religious knowledge is required and is essential to moral stability and rectitude of character and to community life.

Religion, like science, must progress by reason of the wise solution of new problems arising and requiring solution at each step forward made by mankind. Just as the climbing of mountain peaks reveals at each new summit higher peaks above, in endless progression, so also to the eye of science and religion new vistas and new visions of heights yet to be scaled and explored with their secrets to be laid bare reveal themselves as every advance is gained.

There can be no divergence from the basic laws governing man's research and discoveries as between

religion and science. Just as it is the fact that the Ten Commandments, the doctrine of the Sermon on the Mount, and the principle of the Golden Rule are as true a moral guide to-day as they were when first revealed to man, yet we must not ignore the fact that there was a date when they were for the first time revealed to man and that prior to that date mankind could only act ignorantly of these essential moral laws. Does not this fact agree with the identical corresponding position occupied by science to-day?

The stars shone from the heavens before men of science placed the telescope at the disposal of the astrologer and thereby converted him into an astronomer. The air was the same air before the modern chemist searched out the truth of its chemical composition of oxygen and nitrogen; water was the same water before the chemist discovered that it consisted of hydrogen and oxygen and so converted the capped and robed alchemist, with his crucible and cauldron and wizard's surroundings of stuffed and suspended crocodiles and snakes and his search after the philosopher's stone into the modern analytical chemist who banishes belief in magic and lays bare for us the immutable laws of the physical universe by investigation of facts and research after truth.

Life may have lost somewhat of its charm of poetry, tradition, and fairy story and song. Life may have become more matter-of-fact, and consequently have lost somewhat of its romance when the chemist resolved air into 78 per cent. or over of nitrogen, 21 per cent. of oxygen, and 1 per cent. or under of other gases, than was the case at the time when air to our fathers was known only as the breath of heaven that rustled the leaves of trees, the waving corn, and that fanned our faces when in gentle mood; and that equally at other times, when in angry mood, could be the hurricane or the storm that levelled mighty oaks to the ground, overturned houses and drove ships and sailors, despite their skill, to destruction.

Also when the chemist resolved water into two parts of hydrogen and one part of oxygen, he did not add to the poetry of life in sea or lake, river or brook, clouds or rain. When the scientist harnessed for service of man that unknown power we call electricity, he detracted from the poetry and mystery of the lightning-flash. But then the scientist, by his probing into what we call vaguely the secrets of nature, if he has not contributed thereby to the poetry, song, and day-dreams of life, has rendered life more liveable by giving, through knowledge, greater control over the forces of nature.

The night has become as the day, the link boy has been replaced by the incandescent lamp, the faggot and tallow candle by the electric light. In short, if life has lost somewhat of its poetry, it has more than made up for this by becoming infinitely more liveable and by life itself lengthening whilst its rightful joys and pleasures have deepened and broadened.

This does not mean antagonism between science and art, but rather that the artist does not move quite as quickly as the scientist, because art is founded largely on traditions of past ages and the interpretation of old masters. The modern artist has to adapt himself to the new light science has thrown on life. He is at present like a man who has been living in the shades and shadows of the woods and forests, and who has now the full glare of brilliant sunshine dazzling his vision. He cannot see, until his eyes become accustomed to the change, as well as he saw previously in the semi-darkness. But the artist in painting, sculpture, or architecture is rapidly recovering his vision for beauty in modernity, and his poiso in relation to the beauty of scientific truth.

And equally will this be the case with the professors of religion. They may to-day be a little blinded by the flood of light with which the modern revelations of science have dazzled mankind in a rapidity of sequence that it was inevitable must prove disturbing to ethical balance.

But if professors of religion have not kept pace with the advances of science in the ethical and moral sphere, still less have the professors—if I may apply this academic phrase—of industrialism in modern manufacturing actvities. When one considers the revolutionary change that has been created by new and better methods of production placed at the disposal of manufacturers by inventors, we manufacturers must confess with shame that improved methods of production have not resulted in equally improved conditions of life for the workers in factories.

It almost looks as if, in climbing the mountain peaks, hand in hand with the scientists, the manufacturer long ago had reached for his ethical progress what is known in forestry as the timber line and that, until the manufacturer can overcome limitations of his outlook on the human element in production, he may be a drag on science in its desi and efforts to confer better living conditions o mankind.

It is recorded that on the high borders of the timb line limit of mountain peaks some twenty to th rings have been counted upon a gnarled and twi forest tree scarcely four inches in height—so th had taken twenty to thirty years to produce u four inches in height of timber.

And when we consider all the storms of snow wind and struggle for existence that the st unconquerable vitality of the forest tree has resi and that it has, in spite of almost impossible condit of life, achieved even some growth, however s then instead of scorn for this tiny forest tree of twenty years of age we have feelings of admirati and respect for its courage, vitality, and persistenc And we ought to have the same feelings towards o manufacturers in spite of little progress made in th ethical relationship with the human element in th factories and workshops. There has been so growth and progress, gnarled and stunted, but s growth and advancement are evident on all sides

The manufacturers, during the last 200 yea had to meet the calls of new and better machine economical in production but making ever-grow demands for more and more capital. Their wh energies were, like the tree at the timber lin

sorbed during the eighteenth and nineteenth cen-ries in a never-ending struggle against adverse nditions, and in facing the competition of the whole orld, with limited capital and ever-increasing mands for more capital to provide new and better ildings, plant, machinery, and more ample stocks.

What surprise then if the eighteenth and nineteenth ntury manufacturers, dragged along by discoveries science, should, by the exigencies of the laws of lf-preservation, be only able to produce a gnarled d twisted stunted growth in the organisation of eir relationship to the human element in productive terprise.

We already, on the dawn of the twentieth century, e in the first twenty years of its history a greater ogress towards a higher realisation of the import-nce of better relations with humanity in industry an was made in the preceding two hundred years.

But the possibilities of economical production that n be achieved by giving even more attention to e welfare of the man behind the machine than to e care of the machine itself has yet to be fully alised. The manufacturer who neglected the care his mechanical implements of production would be ughed at and scorned as an example of waste and of efficiency. But the manufacturer who neglects give thought and care to the welfare and happiness the men and women employed in his productive ctories would be neither scorned nor laughed at as example of waste and inefficiency, but might even n a high regard and respect as a keen, hardheaded siness man with no maudlin sentiment about him, d rather as a thrifty model to imitate than a ngerous example to avoid.

It seems to myself that what we manufacturers eatly need is what is known in chemical science as a talyst to join together in united power for welfare, ogress, and prosperity so-called capital and labour.

The world's further industrial progress requires a el to discover the ethical catalyst to achieve y in the science of humanity such as Messel tigated and developed in the science of chemistry. ce is rightly often described as knowledge applied e phenomena of nature. Nature has no greater omena than what we call human nature, for in ords of the Lancashire man, "There's nowt so as folk."

e main facts to guide research for the right l catalyst have been known long ages ago, bly hundreds of thousands of years before s committed to stone the Ten Commandments for n's guidance. But these main ethical laws are rely the alphabet of the science that makes sible the living together of human beings in mmunities and their harmonious working for the efit not of selfish selves, but on lines of enlightened -interest that seeks the good of self on the solid is of unselfish work for others.

All motives spring from the law of self-preservation t has been deeply planted by an all-wise Creator each and every human breast; otherwise human ngs long ages ago would have ceased to continue to st. To quote the words of Shakespeare: "Self-e, my liege, is not so vile a sin as self-neglecting."

But narrow, selfish methods of self-preservation have always failed to achieve even their own narrow, selfish aims and objects. It has been only by the application of the principles of the Sermon on the Mount and of the practice of the Golden Rule that self-preservation in its widest and truest sense is possible.

Material science has outgrown disproportionately spiritual science. Let us remember that, as the poet Goldsmith has affirmed, and as experience has proved :—

"All that Freedom's highest aims can reach
Is but to lay proportion'd loads on each;
Hence, should one Order disproportion'd grow,
Its double weight must ruin all below."

Prof. Armstrong, in his thoughtful Messel Lecture given two years ago, gave us a vivid picture of Rudolph Messel, whose life-work and memory this Society has honoured itself in honouring, and there is one sentence therein that seems to me to be worthy of inscribing in letters of gold in the board room of every manufacturing business enterprise and activity. These words describe Rudolph Messel as :—

"Generous and ever thoughtful of others, unselfish to a degree, he had little thought for himself and a hatred of all display; living among them, he knew his workpeople and was in sympathy with them; hence his popularity and power."

A few paragraphs further on we learn that Messel told Prof. Armstrong that he had been enabled to abandon the use of special appliances for the supply of gases in due proportion in one of his processes by having his attention called by his workman-foreman to the fact that the plant worked better when air was supplied in excess. Surely we could have no better illustration of the direct and important benefit of the "Messel touch," and his rule of knowing his work-people and keeping himself in sympathy with them.

Prof. Armstrong, in another part of the same lecture, informs those, like myself, ignorant of the laws of chemical action and reaction :—

"That it may now be asserted that hydrogen and oxygen cannot interact, and that to determine inter-action a third component must be introduced into the system."

As this fact is true and an accepted law of mere chemical elements and their interaction, it is still more true of the human elements in the workshop.

And surely this "catalyst," to ensure interaction, can best be provided by religion and the teaching of the Sermon on the Mount and practise of the Golden Rule. What the business world requires to-day is a Messel, a Newton, or a Faraday of religion to investi-gate this pressing human problem of the modern workshop.

Professors of religion are quite detached from even the suspicion of personal interest or greed of gain, biased thought, in investigating and exploring impartially and impersonally all avenues likely to lead to the discovery of the true "catalyst" for human relationship in the workshop.

At first thought it would seem that sympathy might be found to be the catalyst that would induce

interaction in the human elements of production called capital and labour. But just as Messel the scientist must have met with many disappointments in chemical research, so will the ethical scientist inevitably meet with corresponding but more distressing disappointments in his researches into the solution of ethical problems, the greater difficulties of which are inevitable because of the ever-changing nature and variations in types of humanity and their resulting, ever varying, response to the same influences even under the same circumstances.

In other words, hydrogen and oxygen, when they are made to interact by a suitable electrolytic process, must, as far as my chemical knowledge carries me, always result in the production of water in definite proportions of two atoms of hydrogen to one of oxygen.

But human sympathy with, say, "A" may result in increasing "A's" power of resistance to adverse circumstances, whilst the same sympathy towards "B" may result in the weakening of "B's" personal power of resistance to adverse circumstances. Every wise father and mother has studied these variations in responses to sympathy and endeavours to guide their training and actions accordingly.

There is no, shall I say, "catalyst" known to us —other than religious truths—to induce interaction between humans that can equally be depended upon to give so closely similar results under similar circumstances with similar human elements than the teachings of the Sermon on the Mount and the practice of the Golden Rule.

I remember hearing the following story when quite a youngster, relating to the wife of a cotton manufacturer who, even in those early days, took a personal interest in the workers at her husband's cotton mill. This well-intentioned lady heard that the twelve-year-old daughter of a spinner in the mill was ill, so she at once made a visit to the home, the door of the cottage was opened by the wife of the spinner, who invited the lady inside and set her best chair for her to sit in. Inquiring about the daughter, the mother replied, "Ay oo's none weel but th' doctor says it's nowt much nobbut oo's o'ergrown hur strength and a wik or fortni't at Blackpool would put hur reet." "Well, won't you send her to Blackpool?" "Eh, missus, it 'ud take a heap o' brass for that and we connut afford it." "Do you know anyone your daughter could board with in Blackpool?" "Oo ey oo could board with Missus Ainscough; I know hur weel. She keeps a lodging house and oo'd be all reet wi' hur." "Well, look here, I'll pay all expenses of railway fare and board for a month, so send your daughter to-morrow whilst the summer weather is on, for a month to Blackpool." "Weel, Oi'll think about it, but Oi connut say neauw." And so the benevolent cotton millowner's wife was chilled as if a bucket of cold water had been thrown over her by this reception of her solution of the difficulty the spinner's wife had in providing ways and means for following the doctor's advice.

But as soon as the millowner's wife had left her cottage the mother called in her friends and neighbours and said, "Oi've just had the gaffer's missus in asking after our lassie, and when Oi told hur there were nowt much wrong wi' hur and t' doctor wanted us to send hur to Blackpool for a wik or two, oo said oo'd pay all t' expenses of railway fares and lodging-money for hur for a month, and Oi told hur Oi'd think about it, but Oi've thowt and Oi've thowt, and Oi connut see what gaffer's missus can make out of sending our lassie to Blackpool."

Yes, humanity is always looking for selfish unworthy motives as attached to every helping hand extended in sympathy.

The fact is we are all like minnows swimming in the world of our own little brook. It is a sma selfish world and each minnow is absorbed in tl tasks of its daily life and food supply. What c these minnows know of the great oceans of li beyond the brook which feed the clouds with water which in turn come down in grateful showers on hillside, valley, and meadow, and, after providing needed moisture for abundant harvests for man, finally reach the brooks and rivers and hence return to the seas from which they came.

It is not the selfish efforts of each minnow and their absorption in their daily tasks of life and food supply that is all-important, but the great ocean the clouds and the rain, without which the broo would soon become no better than a dry gutter an all minnows perish. The things of real importanc to each of us are not the things that are seen, br the things that are not seen. Every manufacture sees and knows intimately his plant, machinery an the bricks and mortar of his workshop, but he do not equally have visible to his consciousness tl mind of those associated with him in the worksho and yet the mind and soul of those associated wi him are as all-important to the efficiency of l productive enterprises as is the great ocean to very existence of the minnow.

Whilst we are living in the age of opportu it is equally true we live in the age of uncertai If we could only link up together this great of opportunity free from uncertainty, then we citi of the British Empire—the Empire of opportuni with certainty in application of the truths of Christian religion in their bearing on human then we should liberate forces for welfare and ha ness in the twentieth century more powerful greater than ever known in previous history mankind.

Take one well established scientific fact— there can be no intake without correspondin outflow—the very spirit of the modern busine mind, hard as granite and keen as blade of ste seems to be founded on a belief in the very opposi thesis, namely, taking in all that can be got a giving out as little as may be. To get the great amount of work in the longest hours for the minim pay possible is thought "good business" by t hard-headed business man. And equally to give t smallest amount of work in the shortest hours the maximum pay obtainable by force or thr of strikes is thought to be "good business" organised labour unions on behalf of the employee.

We know that both are contrary to scientific uths and that there can be no permanent intake ithout corresponding outflow.

Such policies make of mankind a morass of bog · a dead sea of barren shores incapable of yielding ›mfort or happiness.

Our scientists have devoted themselves hitherto ainly to the creation of better means for cheaper oduction and to harnessing the forces of the ıysical world to man's service. These have been ıe lines along which modern science—and especially ıemical science—has explored and progressed.

And the very existence of civilised life in towns d cities has only been rendered possible by the earches of chemists and others into the physical s of the material world to ensure that mankind ght be enabled to live in harmony with these laws. ut the most important branch of all knowledge — ıankind and his human nature—has been entirely eglected, and not one human in ten thousand nderstands the basis of those laws that govern hical life and govern it just as certainly as does ıe law of gravitation govern the physical world.

Even in regard to physical life, it is doubtful as many as one human in ten thousand would ›rrectly assign on their relative values the respective ›sition of eating, drinking, and breathing. Most ›uld place the order as just given regardless of the t that humans can exist for seven weeks or longer ithout food provided they receive air and water, for seven days without water provided they receive r, but cannot exist for seven minutes without air.

Equally true is it that few manufacturers realise at to labour under conditions that give happiness d contentment to the human mind, enables the ly to perform its daily task with ease and long urance; but to entail on the worker conditions labour that destroy happiness and produce dis- ent—that then the efficient performance of the y tasks becomes impossible. I believe the ving experiment has often been tried on walking rsions with children and in other forms on many ric occasions by generals in high command with adult troopers, or by hardened Arctic explorers their men, when their men were living under tions of existence almost beyond human rance—relief from fatigue being founded on ›ying the mind on happiness and so bringing ved endurance and strength to the body. To ibe the experiment most easily tried by any of I will take the case of very young children, but response is the same in all cases where the policy adopted of interesting the mind beyond the igues and pains of the moment. A teacher has scribed how that taking his class of very small ys a long walk into the country, so long as the rney was outwards into new scenes none com- ained of being tired or wished to return home- rds, but almost immediately the return journey gan first one and then another of the kiddies mplained of fatigue and some even asked to be rried, as they declared they could not walk any nger. A brain-wave came to the teacher—so he gathered sticks lying around and made for each kid a hobby-horse—chose for them a leader and so, each kid astride his own stick as a hobby-horse, they all pranced gaily home, their previous weariness forgotten in the exhilaration of play, and all regretting when the school-house was reached.

Modern workshop conditions of production are essential to the clothing, housing, transportation and feeding of humans under modern civilisation. But workshop life soon becomes brain fag and weariness. Many suppose that the discontent of the modern workshop operative is always in the direction of a desire for shorter hours and greater pay than those they are at that moment receiving, and so thereby to attain better conditions of life.

But this is only partly true, for this discontent is just as keenly felt to-day—nay, even more so than a century ago, when labour toiled for twelve hours a day as compared with the usual eight hours now, and when wages were one-third or one-quarter the average wage of to-day, with the then price of bread higher than to-day, whilst conditions of modern life are infinitely better than the ratio of increase of wages would appear to indicate. So higher wages and shorter hours are no substitute for lack of mental stimulus towards happiness and contentment. A century ago the village blacksmith sang and whistled at his work, though under-paid and under-fed. The modern mechanic does not feel inclined for either. The old stage coach driver cracked his jokes with guard and ostlers, inn-keepers and bar tenders. Not so the modern motor or tramcar driver. For modern life becomes grey without relief or brightness. As to work, the physical toil of the village blacksmith was at least double that of the modern mechanic, and the exertion required to hold and control a team of four horses is much greater than the exertion required from the motor or tramcar driver. The late Mr. Gladstone on one occasion stated that in his youth he had inquired as to which horses on the stage coach routes out of London were worn out the sooner. Was it the horses dragging the coach up Highgate Hill or the horses taking the coach along the level road through Slough? And to his astonishment he found that it was the horses on the easy level road to Slough that were worn out soonest and had to be replaced first, and that it was the horses on the road with the heavy pull up the Highgate Hill route that lasted longest. Therefore, it was monotony that killed. Horses could better endure the heavy collar work up Highgate Hill followed when over the top by the trot down with easy collar and loose traces. And it is monotony of work that kills men as well as horses, for humans are infinitely more liable to corrosion from monotony than horses.

No thought is given to the mental weariness of the human in workshop efficiency. The forces of Niagara ran to waste for countless ages before their potential power was realised and before they were harnessed to the service of mankind. But there is greater potential power for service of mankind in the cultivation of a sound mental outlook and application of knowledge to the human element in

workshops than in all the Niagaras and Victoria Falls or other latent water power the world contains.

And future progress in efficient production can only make further advances by the cultivation and maintenance of states of mind and happiness in workshop employees.

Past ages have seen mankind absorbed on various ideals of brute force, militarism, and conquest. All these ideals have proved unproductive of happiness even to the victorious conquerors. The fact is that only in the performance of service to others and duty to our country can lasting happiness be found. This is just as true to-day as it was a century and a quarter ago, when Nelson hoisted to the masthead the signal "England expects that every man this day will do his duty."

This is a democratic age, and there is no power so absorbingly attractive as the force of a democratic ideal. But democratic ideals would not save modern life if we took away from the twentieth century city modern drainage and water supply—and other knowledge that chemical research had placed at the service of man, for then pestilence, disease, and death would kill off the congested populations of our large modern cities, and civilisation would perish more rapidly than ever did destruction follow victorious conquering armies in past ages, despite democratic ideals. These conditions affect us all—those who live in mansions in Mayfair no less than the slum dwellers—and democratic ideals would not save us. It is only by the knowledge of chemistry and bacteriology that modern civilisation continues to exist at all under modern conditions.

What is wanted to-day, nay, is even still more essential than these, is that there should be corresponding researches undertaken and knowledge and discoveries attained in the ethical life of mankind as in the physical life. The so-called modern socialistic or communistic upheaval is as old as community life itself. All the modern suggested "short-cuts" to welfare and happiness of the people have been tried over and over again and always ended in increasing and never in decreasing human misery and wretchedness.

And yet as far back as records exist of ancient community life in the ages past with all peoples, the basic truths of the Bible when applied to community life have invariably resulted in making possible the attainment of the greatest prosperity, the widest diffusion of happiness with the deepest most abiding joy and the most efficient life attainable by human beings.

Thousands of years before the Christian era we find almost all the moral guides laid down in the Bible had formed the basis of every efficient religious system the world has ever known. The Advent of Christ only laid greater emphasis on these ancient guides for mankind, while adding thereto one hitherto unrecognised outstanding governing truth—the power of gentleness. There was, as far as my knowledge goes, mainly this one new truth, this one new ethical principle brought by Christ to the world, that is not to be found in most of the older systems of religion nor in the Bible prior to the advent of Christ.

Christ for the first time founded His religion on the overwhelming power of gentleness. The religious systems of the world prior to the advent of Christ were founded on the power of force and the strength of the physical man. Community life according to these older systems of religion demanded on "an eye for an eye, a tooth for a tooth," a system of revengeful punishment. It was the Head and Founder of the Christian religion that first directed mankind's attention to the far greater strength and irresistible force of the power of gentleness.

We Christians neglect in the daily relations of community life this fundamental basis of the Christian religion and believe as firmly to-day as ever in the world's history that whilst it may be true that "thrice armed is he who hath his quarrel just," the modern doctrine that "four times he who gets his blow in fust" has best chances of ultimate victory. And this after centuries of the world's experience of its utter unsoundness.

We note this mistaken ethical outlook on life equally trusted in by professors of religion as by business men under our so-called but misnamed Christian religion. It has been well said that whilst this policy may, if it succeeds, "get even with" one's opponent, the higher power of gentleness carries one far ahead of all opponents. Until this power of gentleness is acknowledged as the fundamental truth of the gospel of Christ's teachings and becomes the basis of the teachings of the Clergy of our Christian Religion, our so-called Christian Religion can show no advance upon the old worn-out religions that have preceded it.

It is little wonder that science has outstripped religion in the service of mankind. We have no corresponding neglect by professors of science of the basic laws of the physical world. It is little more than two centuries ago since men of science placed at the service of man the discovery of the law of gravitation. It is less than one century ago since men of science placed at the service of man the discovery of the power of electricity. It is less than half a century ago since men of science placed at the service of man their discoveries of internal combustion engines, a discovery that has made possible the conquest of the air, and of flight through the air hitherto available for birds only. It is less than a quarter of a century ago since men of science placed at the service of man their discoveries in radioactivity, wireless telegraphy, and wireless telephones.

But these great discoveries of science once placed at the service of man and their solid foundation of truth firmly established, man has never failed to apply them to his daily community life, with the result that in less than two centuries of science the world has been made a better world physically for mankind, especially for mankind living in cities and towns, than all the preceding centuries from the time of man's first advent on this planet.

This is true only of physical life—in the moral and ethical life man has made no such corresponding advancement. Brute force, costly armaments and wars, revenge and cruelty have by means of the discovery of science been made more brutal, more

ruel, more powerful, until their ruinous modern ostliness is to-day the only effective check on their perations.

Now let us suppose that men of science after the iscovery of, say, the law of gravitation, or the ervice of steam or electricity, had treated these iscoveries as not fundamental truths of science be applied with confidence in their stability. ould we not have had chaos and confusion in the orld of science, as we have confusion and chaos in e world of religion ?

Is it not a fact that Bishops and Clergy of all nominations and forms and variations in the aching of our Christian religion have almost iversally acted, and some even spoken, as if they lieved that the teachings of Christ, as expounded His Sermon on the Mount, and His teachings of power of gentleness, were not fundamental ristianity ? Have not we, poor ignorant laymen, oping vainly in the dark for ethical guiding prinples, been told by Bishops and Clergy of all so-called ristian denominations, that modern community e cannot be founded on these principles nor successl business be established on their practice ?

The man of science does not "wobble" on the sic law of gravitation. On the contrary, he builds hole series of movements and actions founded on truth of the law of gravitation. The man of nce does not limit the action of the law of gravita- to certain circumstances that appear favourable s successful action. On the contrary, he declares inevitable results that will follow any disregard man of this basic law under any and every circumnce of life. He declares with no uncertain sound if the maintenance of the dykes in Holland were lected, the operation of the law of gravitation ld result in the submergence of Holland under inrushing waters of the ocean ; that if, by careless alculation, the engineer planning bridge or voir misjudged wind and flood pressure and t to be supported, there would be no exception operation of the laws of gravitation and that ng bridge or bursting reservoir embankment swiftly bring death, suffering, and ruin on nt sufferers.

the teachings of the Sermon on the Mount e practise of the Golden Rule are just as cold l laws for the "man of the world" as is the gravitation for the man of science, there is peal to sentiment or to emotionalism in either. o equally with all the teachings of Christ. centuries religion has been viewed as an appeal the emotions, and not as expounding cold basic s to govern humanity in relation to individual and mmunity life. Yet such laws of religion are olutely free from all sentimental emotionalism.

We require to-day more than ever to realise that ist was the greatest Ethical Scientist the world ever produced, and that His teachings are ntific ethical truths that govern the conduct of . That to neglect or disregard these scientific ical truths can only bring speedy disaster on mand as certainly as would disregard of the law of vitation. The direct result of the teaching of men of science is that neither individuals nor nations fool with the law of gravitation, whilst as the direct result of the introduction by the Church of emotionalism into religion and neglect of the teachings of Christ there has been substituted, for the cold, scientific, immutable and immovable ethical teachings of Christ, a certain maudlin emotionalism which brings the Christian religion into disrepute with thinkers, scientists, and practical business men.

In all my readings of the Gospels I have failed to find one single occasion when Christ, in His teachings of the laws of religion, acted other than as a man of science in his teachings would have acted, when considering with full knowledge the inevitable unchanging and eternal action of the laws of science.

The neglect of the scientific truths of Christ's doctrines and the substitution of sentiment and emotionalism therefore has no foundation in Christ's teachings, and it is for Clergy and Ministers of all shades and variations of denominational religion to recognise the scientific basis of the Christian religion; not till then will the progress of mankind towards the realisation of the fullest measure of happiness and well-being in community life be possible.

There is nothing savouring of materialism in this view. But, in fact, our Christian religion as taught and preached to-day is not so much in danger from errors of materialism as from errors of maudlin sentimentalism and emotionalism.

Neither is there danger to Christianity to be feared from what is called denominationalism. Just as flowers, trees, grass, and all varieties of plants derive their life and growth from the same Divine source—sun, rain, air, and earth—and yet are not from that fact prevented from producing an infinite variety of flowers, trees, grass, and plants without schism, infidelity, or departure from the laws of the Divine source from which they derive their life and growth. And just as the man of science can produce an infinite variety of movements and types of machinery suited to all purposes for the service of man, yet each founded on strict fidelity and conformity to the laws of gravitation, and other physical laws, and without schism, infidelity, or departure from the laws of science, so can there exist denominationalism in religions founded on the teaching of Christ without schism or infidelity or departure from the Divine laws of religion.

It was intended by our Creator that there should be infinite variety in the physical world and no uniformity, and so it was intended, in my humble opinion, that there should be infinite variety and absence of uniformity in the religious world. And yet, with strictest obedience to the basic laws that govern either and both. The basic laws of the Creator in both the religious and scientific truths of the Universe are too powerful, too great, and too grand to be limited to any one single approach.

In a few months I go to the Congo, and shall be living for a few weeks amongst a people whose life has not yet, in their native forests, developed beyond what we call "the Stone Age." Witchcraft there takes the place of science. If it rains more than they require, then they search out a witch doctor to stop

rain. If they suffer from drought, they search out a witch doctor to bring rain. If disease and death seize a village, some enemy has bewitched them, and they seek out a witch doctor to create a more powerful fetish to break the witchcraft of the enemy.

To primitive man every volcano, lightning flash, or thunder peal, every tree, sea, river, lake, or mountain is a god, and just as primitive man is always cruel and revengeful, so is the primitive man's god cruel and revengeful. Primitive man mixes up science and religion, and is unable to interpret the phenomena of the physical world other than on lines of his primitive witchcraft religion. When a twentieth-century man visits the Congo with motor-car, steamboat, or aeroplane, the Congo native classes all together as "white man's magic."

Perhaps to fortieth-century man the scientific and religious knowledge, say, of us who live in the twentieth century, will appear just as crude and immature as appears to-day that of the Congo native to us of the twentieth century.

And yet there will be no change in the Divine Laws governing life either in science or in religion nor governing humanity. It will be merely a better knowledge of these laws and a greater fidelity and obedience to them that will raise the fortieth-century man to a pinnacle from which he will see twentieth-century man's religious and scientific knowledge to have been founded on colossal ignorance.

And so this grand old world will progress, but always and only along lines of all well-defined basic laws and immutable immortal truths.

The lines by Prof. Carruth will express my meaning better than any feeble words of mine :—

"A fire mist and a planet,
A crystal and a cell;
A jellyfish and a saurian,
And caves where cave men dwell;
Then a sense of law and beauty,
And a face turned from the clod—
Some call it Evolution—
And others call it God."

DISCUSSION.

THE PRESIDENT asked Prof. Armstrong to propose a vote of thanks to Lord Leverhulme.

PROF. H. E. ARMSTRONG said that they had just listened to a very remarkable address, one which was destined to be heard not only in the Society but throughout the world. Lord Leverhulme had not only shown himself to be a philosopher, but a scientific Christian, and his address had been extraordinarily full of literary charm. He had coined a very remarkable phrase, a very biting phrase, which was likely to live, in speaking of the Church's maladministration of the Bible.

He believed that the original donor of this lectureship would have looked upon their choice of the Medallist as the greatest step forward the Society had ever taken towards achieving its inevitable purpose, that of uniting chemical science with industry, in leading the two to march as twin brothers with only one end in view. It would have been easy [illegible] have maintained an academic succession, to have given a narrow interpretation of science, but instead they had wisely taken science as meaning wisdom, real knowledge, vital knowledge, knowledge made effective. Let them just consider what Lord Leverhulme had done. A man who had made the experiments he had made, experiments on a very large scale, more often than not with success, must be possessed of the scientific mind, must have the gift of imagination, must be a logician, a man worthy to be called into the fraternity of science.

Viscount Leverhulme had done them the honour of accepting the award of the Messel Medal in recognition of his services to science in making it available for the public good by the exercise of his gift of imagination and of his all-compelling organising power. He had that day been given the Freedom of their Corporation; they asked him henceforth to be a warrior in their ranks. He had organised an industry; they asked him to help them organise their science, and aid them in bringing together the various unassociated, if not scattered, conflicting elements, and in uniting them under one flag under one roof.

It was not necessary to ask the members to return their thanks to Lord Leverhulme. They had done so already in a very marked manner, and he was sure that Lord Leverhulme would go from the meeting with the feeling that he had indeed done a great work on behalf of the Society.

LORD LEVERHULME said that he was overwhelmed by the far too generous words they had applied to him in proposing the vote of thanks, and he was very conscious of his unworthiness of them. He was very grateful for the patient hearing they had given him in dealing with a subject he had found, when he had come to attempt to deal with it, to be overwhelming. The object he had had in view in undertaking the task would have been accomplished beyond [illegible] wildest ambition if it succeeded, in a world of indus[illegible] during the twentieth century, in securing attention [illegible] consideration to the man behind the machine. [illegible] the nineteenth century the attention of industry [illegible] been devoted to the machines. He believed th[illegible] the twentieth century onwards their greatest achi[illegible]ment would be to pay even more attention to the [illegible] behind the machine than to the machine itself.

A MODIFIED THERMO-REGULATOR

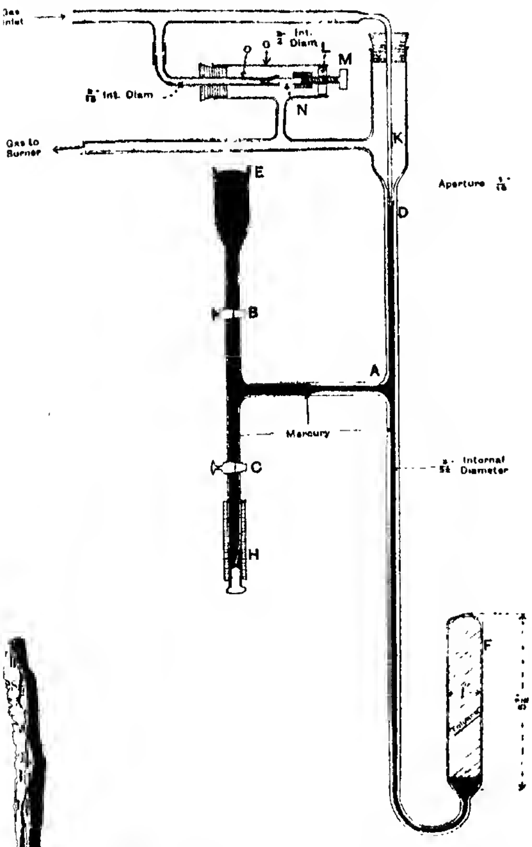
BY J. HUME, B.SC., A.I.C.

For certain dilatometric experiments it was necessary to have some means of keeping the temperature of a water-bath constant for long periods after successive small increases of temperature. To this end a thermo-regulator was devised, as shown in the diagram.

To a thermo-regulator of the usual type for gas heating a side-tube was attached at A, carrying two stop-cocks, B and C, and extending to about 1 in. above the level of D.

The apparatus was filled at atmospheric temperature with toluene and mercury to the extent shown

…mmersed in a bath at a temperature below the …west temperature required for the experiments, …d the stop-cock, B, was opened slightly. (As …e temperature required was below atmospheric, …ore mercury flowed into the tube, AD.) When …e mercury rose to D, the cock, B, was closed. …he bulb, F, was then immersed in the bath to be …sed for the experiments, and was connected to the …s supply and to the burner. The by-pass, G, …as opened very slightly and the burner lighted. …s the apparatus was set for a temperature lower



… the first working temperature, mercury had to …awn off, and this was done by opening cock C …e. The level of the mercury at D was allowed …l very slightly and cock C was closed. The …rature of the bath was then allowed to rise …ar as it would, and the process repeated till the …uired temperature was reached. During this …liminary adjustment, a rough calibration was …de by sticking a narrow strip of paper on the …e at D, and marking the level to which the …rcury fell and noting the consequent rise in …perature of the bath. It was then a simple …tter to raise the temperature by any amount …wn to a tenth of a degree at a time, and to keep …constant for any required length of time. The …rmometer used was graduated in tenths of a …ree, and could be read to 0·02°, and on this no …iation in the temperature of the bath could be noted, once equilibrium was reached after each alteration of the mercury level.

It was found to be difficult to manipulate the cock, C, so as to draw off a small enough quantity of mercury, so a short length of rubber pressure-tubing, H, was plugged at one end and slipped on to the nozzle below C. The nozzle was previously filled with mercury and the tubing was put on, using a piece of fine copper wire to allow air to escape, as is done in connecting up gas burettes and pipettes. When it was necessary to raise the bath temperature, the cock, C, was opened and the pressure tubing, H, pulled downwards to a slight extent, causing the mercury at D to fall. If it fell too far, it could be raised accurately to any desired level by pinching the pressure tubing and then closing the stop-cock.

If the necessity occurred to lower the temperature, mercury was admitted through B, till the level at D was too high. Then fine adjustment was obtained by using the cock, C, and the pressure-tubing, H.

When the regulator was used over a great range of temperature, a point was reached where the tube, K, could not pass sufficient gas. To overcome this difficulty an easily controlled by-pass valve, as shown at G, was fitted in place of the usual screw-clip and rubber-tubing. This valve was made by taking a piece of wide glass tubing with a side-tube, and fixing into one end of it with sealing wax a nut, L, with a bolt, M. To the point of the bolt was fixed with pressure-tubing a very gradually tapering piece of glass rod, N, which was ground into the end of the glass tube, O. By means of this valve, the rate of flow of gas could be altered by very small amounts.

The apparatus was used with great success over a range of temperature from 6° to 40°. For temperatures below 20° tap water at 4·5° to 5·5° was run into the bath, using a constant-level siphon inflow, and water was run out by means of a constant-level siphon outflow. This constant flow of cold water through the bath, working in conjunction with the flame controlled by the thermo-regulator, kept the temperature constant within the limits mentioned. The bath contained about 12 litres of water, and was, of course, fitted with an efficient stirrer.

When working at temperatures below atmospheric, drops of condensed moisture from the under-side of the bath frequently extinguished the flame, until it was protected by a small disc of tin-plate supported about 2½ in. directly above it.

The University,
Leeds.

THE ANALYSIS OF COMMERCIAL BUTYL ALCOHOL.

BY C. H. SPIERS, M.A., B.SC.

At one period butyl alcohol, from the butyl alcohol–acetone fermentation, was marketed in a hydrous form nominally containing 90% by volume of butyl alcohol. This commercial alcohol contained, besides water, acetone and ethyl alcohol as impurities; also isopropyl alcohol was sometimes

present. The product varied in composition between fairly wide limits. The following figures represent the compositions of two samples :—

	Composition by volume. A.	B.
Butyl alcohol	85 0	90 0
Ethyl alcohol	7 0	2 5
Acetone	1 0	1·0
Water	7 0	6 5

The presence of ethyl alcohol and acetone renders the determination of the butyl alcohol by ordinary fractionation and dehydration processes exceedingly tedious and at the best unreliable. Indeed one process, reputed to give accurate results and taking a day or more, revealed the presence of ethyl alcohol in a synthetic mixture free from it. The main difficulty perhaps arises from the apparent impossibility of separating ethyl alcohol, b.p. 78°, from the constant boiling point mixture of butyl alcohol and water, b.p. 92°, even with the most efficient still-heads.

Some preliminary experiments showed that butyl alcohol could be determined reasonably accurately by a process of distillation with benzene. The work, however, was interrupted before the method had been exhaustively tested. Since butyl alcohol is now a solvent produced on a considerable scale, it is thought that the publication of the results obtained may be of use.

Young and Fortey (Chem. Soc. Trans., 1902, 81, 739) describe the following mixtures of constant boiling point :—

Constituent.	B.p.	Percentage composition by weight. Alcohol.	Benzene.	Water.
Ethyl alcohol, benzene, water	64 86°	18 5	74 1	7 4
Ethyl alcohol, benzene	68 24°	32 36	67·64	—
Isopropyl alcohol, benzene, water	66·51°	18·7	73 8	7 5
Isopropyl alcohol, benzene	71 92°	33 3	66 7	—
Benzene, water	69 25°	—	91·17	8 83

On the other hand, butyl alcohol forms neither a ternary constant-boiling mixture with benzene and water nor a binary mixture with benzene.* All the above boiling points are well below that of benzene and that of the constant-boiling mixture of butyl alcohol and water; so that if sufficient benzene be added to crude butyl alcohol and the mixture fractionated, all the lower alcohols and the water (and also the acetone) should pass over before any butyl alcohol distils and the latter would then only have to be separated from any excess of benzene that has been employed. This should be an easy matter with over 36° difference in the boiling points. Further the weight of liquid left in the still, after distilling to the mean temperature between the boiling points of butyl alcohol and benzene, should be equal to the weight of butyl alcohol present in the sample (Young and Fortey, *ibid.*, 1902, 81, 752).

Method.—A suitable weighed quantity (100 c.c.) of the alcohol is mixed with a suitable weighed quantity of benzene and the mixture slowly fractionated through an efficient still-head. The distillate up to 100° is weighed. The weight of the butyl alcohol present in the original sample is the difference between the weight of the benzene and crude butyl alcohol and the weight of the distillate to 100.°

The amount of benzene to be added must be gauged by the specific gravity of the sample, which gives some idea as to the water content. 100 c.c. of benzene will carry over 8·42 c.c. of water in the absence of ethyl alcohol, and 8·7 c.c. of water and 27 c.c. of ethyl alcohol if ethyl alcohol is present. The process may also be used in the preparation of anhydrous butyl alcohol.

Experimental.

The following experiments were carried out with a Raschig column 68 cm. long. The rate of distillation was 30—40 drops per minute, except in expt. 1, where the rate was 20—30 drops per minute.

Composition of liquid.		Benzene added.	Total weight.	Distillate to 100°.	Weight of butyl alcohol. By diff.	Actually present
	g.	g.	g.	g.	g.	g.
Butyl alcohol	81 2	44·4	125 6	44 8	80 8	81·2
Butyl alcohol Water	81 2 9 95	133·55	224 7	144·4	80·3	81·2
Butyl alcohol Water Ethyl alcohol	81·1 9·95 3 95	133·45	228 45	147 4	81·05	81 1
Butyl alcohol Water Ethyl alcohol Acetone	81·15 9·95 4 0 4 0	133·2	232·3	152·05	80 25	81·1

There is an extremely rapid rise of temperatur[illegible] between 80° and 117°. The rate of distillation wi[illegible] of course, depend on the efficiency of the still-he[illegible] Thus with the above column a rate of 1–2 dr[illegible] per second does not give such a good separat[illegible] of the benzene and butyl alcohol. It will be [illegible] served that the method gives the content of b[illegible] alcohol with an error of less than 1%.

To determine the lower alcohols and acet[illegible] the benzene distillate can be treated as descr[illegible] by Young and Fortey (*loc. cit.*). The acetone [illegible] the aqueous solution thereby obtained can be de[illegible]mined by any of the standard methods, whilst [illegible] alcohol can be determined by means of the ta[illegible] of Bushill (J., 1923, 216 T).

These experiments were carried out at H.M. Chiswick Laboratory, D.E.S., during 1917, and the author's thanks are due to Prof. J. T. Hewitt, the director of the laboratory, for his helpful advice and for permission to publish these results.

* Young and Fortey show that isobutyl alcohol, b.p. 108 06°, does not form a ternary constant-boiling mixture and that the binary mixture of benzene and isobutyl alcohol boils at 79 84°. Butyl alcohol would therefore not be expected to form either a binary or a ternary constant-boiling mixture.

HE ACTION OF AQUEOUS SULPHUROUS ACID ON LIGNOCELLULOSE.

BY C. F. CROSS AND A. ENGELSTAD.

The production of wood cellulose (pulp) by the sulphite process may be regarded as having been tablished as an industry in 1884: the retrospect 40 years of extension and development justifies critical estimate of the industry as still lacking scientific foundation. Notwithstanding the hievements of the pioneers and the fruitful work a long succession of distinguished technologists, e present-day industry can only be recognised as an borated triumph of chemical engineering.

The primary factors of the process, which are in e main of the domain of pure chemistry, remain defined, that is, in such terms as conform with st principles, and would be set out in textbook m as the ultimate facts and the basis of the lustry in the scientific sense. In evidence, we e only to compare the treatises dealing with the ustry—of which we need only cite the most nt. "Sulfitzellstoff," by Richard Dieckmann, in, 1923,* with those which deal, *e.g.*, with the stries of fats, oils and soaps, of starch, sugars, fermentation, and more particularly with the nical literature of synthetic products.

hat the basis of the process and the industry is ly empirical is shown in the methods employed factory control of the main operation These not based upon the cellulose or main product, pon the lignone-complex (by-product), nor upon rect reaction (sulphonation) which conditions its tion from the cellulose in the soluble form; pon indirect observations upon the inorganic ts employed which more or less, or approxi- y, measure the progress of the reaction in gester in terms of active reagents (SO_2 CaO) pearing, or converted into new combined forms. s the "Mitscherlich" test of the liquor off sample) consists in adding ammonia and ring the volume of precipitated calcium sulphite: st is criticised and modified by Oeman, who a solution of calcium chloride (3%) made kaline with ammonia, which is calculated to recipitate not only the lime in combination as sulphite, but the free sulphur dioxide still present so as calcium sulphite. These tests and the ferences from them have been discussed by Klason, aegglund, Hartof and others, with an accumulation technical literature, in a sense, out of proportion ith a matter of only indirect import.

Moreover, the discussion rather turns upon the ontrol of the process for the avoidance of defective lines of reaction, than for the maintenance of the normal optimum. It is an obvious criticism that this must be secured on positive lines, and primarily on the progressive resolution of the lignocellulose, measured in terms of factors which can be accurately estimated. In this direction nothing is simpler than to measure the residual lignone in the blow-off samples of pulp The washed pulp reduced to a standard wetness by pressure is chlorinated, and after full reaction, the hydrochloric acid formed is determined by titration. In the investigations which are the subject of this paper this test has been found to furnish the basis of a close control, and associated with the determination of the sp. gr. of the liquor, simultaneously blown off and freed from sulphur dioxide by boiling, to give complete and adequate representation of the progress of the digestion process.

In these investigations we have first set ourselves the task of ascertaining what are in effect the reactions which take place between the lignone complex of coniferous wood (lignocellulose) and aqueous sulphurous acid.

From a review of the literature it appears that such systematic investigation, notwithstanding its fundamental importance, has never been undertaken: not only so, but even the textbooks, and the leading authorities in this branch of technology are at variance in their statements on the subject. We cite the following:—

C. Schwalbe ("Chemie der Cellulose," 1911) states, as known, from the patents and publications of Pictet and Brelaz (1883—1885) that a 5–7% solution of SO_2Aq at a range of temperature 88°–100° attacks wood completely, only the cellulose remaining undissolved, but that "carbonisation" of the cellulose takes place with extraordinary ease, even at 90°, since the sulphuric acid produced attacks the cellulose at the pressure employed. The mention of this process occurs in connexion with the Classen method of treating wood with aqueous sulphurous acid for the production of fermentable carbohydrates, and the context carries the suggestion that, as the only differences between the conditions of the two treatments are those of intensity, the Pictet resolution depends upon the intensification of the hydrolytic and deoxidising actions of the sulphur dioxide, with a contribution to the former by the sulphuric acid produced.

The author, it should be stated, may be merely recording a mistaken view for which we (Cross and Bevan) may be responsible, for in our treatment of the Pictet-Brelaz process (1885) the information supplied to us did not warrant the adoption of a direct sulphonation of the lignone complex as the main reaction involved. On this particular point, more-

D

over, we cite a later and more definite statement by H. Ost ("Lehrb. Chem. Technologie," Ed. 8, 1914, p. 475):—

"Schwelligesäure allein schliesst Holz nicht genügend auf, der Kalk ist notig zur Bildung des Sulfonsalzes und zur Neutralisation der stets vorhandenen Schwefelsaure welche als frei Saure den Zellstoff schwärzen würde."

On the other hand, A. Klein (Verh. Zellstoff Papier Chem., 1908, p. 50) makes the general statement that with free sulphurous acid and wood substance, interactions take place of similar order to those of the bisulphite process; and that in the latter an important function of the base (CaO, MgO) is to prevent secondary reactions and decompositions, the products of which cause discoloration of the pulp and liquor.

This statement, which is definite and correct in general terms, is not accompanied by reference to specific investigations, and of such we can only find in the literature a note of a research carried out in 1907 by Seidel (Diss., Dresden), who appears to have employed the acid (SO_2Aq) at much higher concentration (17% SO_2), and to have obtained very imperfect resolutions of the lignocellulose.

As we are not attempting a complete bibliography we cannot notice many publications, which have a certain relevancy; we have cited such as have conveyed to us the conviction that a systematic reinvestigation is required, as a contribution to the very foundations of one of our most important industries. This conviction has been much strengthened by experience of the present state of our knowledge of wood cellulose. Primarily "bisulphite pulp" is a paper maker's raw material, and such control of cellulose quality as the pulp makers have acquired, is directed by and to structural characteristics.

The arrival of viscose, however, erected a new standard based upon chemical constitution, and critical selection according to this standard has also revealed, per contra, the generally low level of quality in this respect of the bisulphite pulps now produced. There is one other consideration upon which a critical revision of the industry is called for, and that is that we still accept the waste of the larger proportion of the by-product as inevitable. Seeing the importance of the lignone complex in the plant world, it remains to us as chemists and therefore economists to continue our endeavours to convert this present waste to industrial value.

We have now to record the preliminary results of our systematic investigations, that is of the interaction of aqueous sulphurous acid (5–8% SO_2) and the lignocelluloses, of these mainly coniferous (spruce) woods, but with incidental comparisons of beech and the simpler prototype of the lignocelluloses, viz., jute. It has also been necessary to investigate the behaviour of the normal cotton cellulose when exposed to the conditions of digestion both with aqueous sulphurous acid and with the standard liquors of the bisulphite processes.

At this juncture, however, we have to limit this record, in view of recent developments which promise to elucidate more completely the mechanism of the reactions, and especially in regard to the production of pulp or cellulose.

At the same time to introduce and call attention, as of precedent interest, to the communication of Dorée and Hall which follows this. By this record of a full investigation of the main by-product, the lignosulphonic acid, it is established clearly (1) that sulphonation is a direct reaction of sulphurous acid as such upon the lignone complex, or rather a specific component group of the complex; (2) the secondary effects, differentiating the by-products of the sul- phurous acid and bisulphite processes, are those of the degree of sulphonation, de-oxidation of ... groups, and condensation of the sulphonated compl...

These points may be usefully illustrated by t... results of a reaction which we studied in the ea... stages of the investigation.

Assuming a certain constitutional analogy betw... the more characteristic groupings of lignocellul... (jute) and cinnamic aldehyde, we investigated t... interaction of this aldehyde and aqueous sulphuro... acid at 100°–110°.

Cinnamic aldehyde and aqueous sulphurous acid.

6·3 g. of the aldehyde and 2·17 g. of SO_2 (mol. ra... 1·4 : 1) in 30 c.c. of aqueous solution were diges... for 24 hours at an average temperature of 110° i... stoppered glass tube.

The products were (A) yellow solution; (B) s... crystals in suspension; (C) dark coloured m... evidently fused at the temperature of digestion.

Of the SO_2 taken, 78·4% is accounted for in co... bination. In A 2·056 g. and in C 0·126 g. as H_2S... B was free from sulphur and identified as ... styryl or cinnamyl alcohol. The weight, 0·243... would represent the production of 0·1766 g. H_2... (conversion of SO_2 to SO_3): in A was determi... 0·160 g. H_2SO_4 produced in the digestion. ... combined SO_3H in A was equivalent to reaction ... 55·8% of the original aldehyde.

The derivatives present were (*a*) the sulp... acid, giving soluble barium salts on boiling ... barium carbonate, (*b*) the additive compound ... aldehyde hydrogen sulphite, decomposed on b... Of the total combined, one-fourth was in ... (*a*) form.

The black cake (C) weighed 2·584 g., 40% o... original weight of aldehyde fusible in wat... 90°–100° and consisting of a mixture of cryst... and tarry condensation products, it has no f... interest than in completing the statistics ... reaction.

Notwithstanding the low molecular ratio of ... sulphurous acid reacting, the degree of reaction ... considerable, and is evidence of an intense co... bining relationship of the acid and the acr... aldehyde groups. Although obvious that benz... CH : CH groups cannot react, the simple aldehy... benzaldehyde, was put under observation ... identical conditions of treatment. After react... there was no evidence of change and the sulph... acid formed, in small amount, was not more t... the equivalent of 3·5% of the aldehyde conve... into alcohol.

These results will be found to have a direct bearing on the main subject of this and the following aper. This main subject is the sulphonation of the gnone complex by interaction with aqueous sulhurous acid, and it is evident that with the aracteristic constituent ketohexene groups, with unsaturated aldehydic side group, which we ve always adopted (Cross and Bevan, "Cellulose" 90, p. 202), and of which cinnamic aldehyde is an alogue, this reaction would be the direct and ajor factor also of the bisulphite processes. On e other hand there are various secondary effects tained in the industrial processes of digesting od with bisulphites; and we have made observas of the reactions with the aqueous and uncomd acid of compounds, which may be presumed e present, formed or liberated as by-products the wood complex.

Dextrose and aqueous sulphurous acid.

Dextrose ($C_6H_{12}O_6$, H_2O) 77·0 g., and SO_2 30·6 g. 450 c.c. (6·8% SO_2), *i.e.*, mol. ratio approximately were heated for 26 hours at 110°.

Of the products 1·017 g. were insoluble. Of this % was soluble in carbon bisulphide and fully ified as sulphur.

Sulphur-oxygen compounds.

rect determination of SO_3 showed the formation ·69 g. Determination after complete removal sidual SO_2 and full oxidation gave an additional . Boiled with barium carbonate in excess the te contained only the barium equivalent of the acid formed (determined by distillation and ion). After oxidation the SO_3 in this filtrate determined and calculated to the original nted to 2·5 g.

is shows the presence of sulphur-oxygen deriv of by-products, not forming salts with barium traces only of sulphonic acids.

breakdown of the dextrose is shown by the solids. These were approximately estimated , and the loss therefore as 70 61 9·0 g.

determination of the residual dextrose by tation and calculation from the alcohol gave 55 g. Phenylhydrazine with onenth part of the original gave a precipitate cold (hydrazone) of 0·234 g.; also in the filtrate 100° (osazone), 1·691 g. The osazone once ised from alcohol had m.p. 203°. The roduct accompanying the residual dextrose ed to the residue, evaporated from the ralised barium carbonate solution, the appear of caramel. It was of no immediate interest haracterise the by-products further.

he reactions determined are of direct bearing the processes of wood digestion whether with lphites or the uncombined acid.

n view of the fact that the by-product liquor the industrial process (bisulphite) contains 1·3% of fermentable hexoses, and that under in conditions of digestion, production of sulphur served, this is more simply explained as resulting direct deoxidation of sulphur dioxide by the organic by-products than by the assumption of complex interactions involving the formation and decomposition of acids of the polythionic series.

Terpenes and aqueous sulphurous acid.

Since the terpenes and condensed derivatives are characteristic secondary components of the wood complex, it was of interest to make observation of any interaction with the aqueous acid.

A tube containing 31·7 g. of turpentine and 375 c.c. of the aqueous acid (8·0% SO_2) was sealed, and heated for 26 hours at 110°. The evidence of reaction was the presence of sulphur, and the hydrocarbon was turbid. Since the reaction contact between the aqueous acid and hydrocarbon could only be small as in the case of the benzaldehyde (*supra*), the presumed conversion to cymene would be small in amount. The production of sulphur was a definite index of a secondary reaction of this order taking place in the cellulose process.

Normal cellulose and aqueous sulphurous acid.

In view of the sensitiveness of the cellulose complex to acids, it is *a priori* obvious that any acid process of digestion of a raw fibrous material for the separation of cellulose, must determine a certain degradation of the cellulose in the course of its isolation.

(*a*) As a preliminary observation a large cutting of a normal bleached calico was enclosed in an extemporised cage of lead tubing, and exposed in a digester to the ordinary conditions of the bisulphite process. At the conclusion of the digestion, the product was carefully removed from its surrounding of "boiled chips," well washed and dried for examination. The cellulose was converted into a fine powder of minute dimensions. On analysis by the standard method the following were determined: Moisture in air-dry state 7·85%; α-cellulose 77·5, β-cellulose 20·7, γ-cellulose 1·8, calculated to 100 of dry cellulose.

The elementary composition was determined by combustion and gave the following figures calculated on ash- and moisture-free substance:—C 43·4; H 6·35%; $5(C_6H_{10}O_5)H_2O$ requires C 43·5, H 6·3%.

(*b*) Similar results were obtained on digestion with the aqueous acid (8·0% SO_2 - free from SO_3) at 110° (pressure 5·4 kg. per sq. cm.)

(*c*) 200 g. of bleached cotton cloth (mull) were digested with excess (10 litres) of a 2% SO_2 solution at 99·5° (pressure 0·23 kg. per sq. cm.) for 12 hours. The cotton lost in weight 15 g., *i.e.*, 7·5 %, and the resistance of the fabric was reduced to 11·9% of the original.

In view of these results it appears important to enquire into the degree of degradation of the natural wood cellulose, in the course of a normal digestion with bisulphites. It is well known to technologists of the craft that the process requires most careful regulation in the last phases of the digestion to conserve the normal optimum of "strength" in the pulp (fibre).

It appears to be an obvious inference from the results above detailed that the wood cellulose,

exposed as it is to long contact with sulphurous acid at the high temperature of the bisulphite processes (125°–145°), must be protected in an important measure by its association with the lignone complex, and in proportion as this is removed to its final minimum (1·0–2·0%), the attack on the cellulose must advance *pari passu*.

This discussion, however, brings us to the most important objective of our investigation, which is to determine the optimum of the conditions of controlling the sulphonation of the lignone by the aqueous acid, to the maximum of conversion, with the least effects of degradation of the cellulose (fibre)

For reasons stated (*supra*) we reserve our full story of the investigations, especially as regards the cellulose or pulp, until we have completed a new series which involves new conditions of action deduced from our first series of experiments.

This first series comprised something like 100 trials carried out in a digester, which is a drawn steel tube, lead-lined, with available volume 14,000 c.c.; this enabled us to treat 1600 g. more or less of spruce chips For such weight the digester was charged with 11 litres of the aqueous acid previously treated where specified for the removal of free sulphuric acid.

The digester is a cylinder around which was wound a spiral of chrome-nickel wire carrying current for the thermo-electric heating, which gives very close control of temperature and pressure. All the factors of digestion being noted, at the conclusion of the digestion, the entire contents of the digester were treated in such a way as to give a complete quantitative account of results both in liquor and by-product and pulp. The pulp was examined more especially by the method of chlorination and by the determination of α- and β-cellulose, and in certain cases by special methods.

The main purpose of our preliminary investigation being the elucidation of the reactions of the digestion process, interest rather centred in the by-product, and the supply to Messrs. Dorée and Hall from time to time of such quantities as were needed for the investigation of constitution, with the larger quantity required for testing in relation to industrial applications.

In regard to these, a number of which have been studied, there are also developments resulting from our new method of digestion, and here again the complete story is reserved for the same reason, viz., that later experience of new forms of the by-product is contributing to the elucidation of the special characteristics of the complex lignonesulphonate in relation to the degree of condensation and its physical properties as a colloid.

As a record of this preliminary investigation we give an abstract of the detailed laboratory report of Dr. Berhom, research chemist, who carried out the operations. All yields are calculated as dry products per cent. original dry material.

Series 1–9.—SO_2 varied from 7·5 to 10·5%. No treatment for removing SO_3. Temperature 100°–115°: duration 18–60 hours. Pulp: average of yields 45%—varied from a free fibre to unresolved chips—and in colour from yellow to brown.

Series 10–14.—SO_2 8·1–8·5%. SO_3 estimated, and converted to Na_2SO_4 by equivalent $NaHSO_3$. Temp.: 100°–115°: Time 26–51 hours. Pulp: yields average 43·5%. Great advance on previous series in regard to colour and disintegration of chips. In one case equal in appearance to the standard of the mill (bisulphite process). But all difficult to bleach.

Series 14–19.—Conditions as above. With hard wood (aspen) and jute fibre, *i.e.*, other types of lignocellulose. The effects were similar. Jute full resolved to ultimate fibres (yield 55% only) with 6% SO_2Aq at 110°–15 hours' digestion.

Series 20–42.—Spruce wood (chips). SO_2 at 6·5–8·5%. Treated for SO_3 to Na_2SO_4. Time varie especially in the phase < 100°, 12 to 48 hours. Pulp yields average 47·5%, but resolution of wood mostly incomplete.

Series 43–44.—SO_2 4·1–4·5% (as in bisulphite liquors)—Temp.: 110° to 140°, 11 to 12 hours. Pulp: very imperfect—wood mostly unresolved.

Series 45–50. *With bisulphite liquor as used in* –4·5% total SO_2 0·5% combined (CaO). The were actually tests of efficiency of the laborato digester and conditions, and as the results in pulp effect were very inferior to those of the mill digeste it was evident that reaction-mass and the conditi of circulation of the liquor have to be reckoned w as factors. It was therefore important to carry the SO_2Aq digestion under mill conditions (7-t digester). The digester with the charge of chi and the complement of solution prepared by absorb SO_2 blown off from bisulphite digesters in w (7·1% SO_2) was kept under close observation dur the digestion (28 hours), the results of analy (blow-off samples) at 2 hour intervals being record for future comparisons.

The pulping effects were satisfactory: the wh charge was finished through the mill operatio there were no "screenings"; the finished sheets from the dryers were of good fibre qual the colour, however, was low and in bleaching consumption of "chlorine" was outside the econ limit.

Series 51–63.—Reverting to the laboratory co tions, the pulp produced under the optimum co tions previously determined was washed and retn to the digester for short treatment with ne sodium sulphite (varied from 0·1 to 5·0% Na 2 hours up to 140°. Determination of yields showed a progressive reduction from 47·5 to 41·5%; with, however, an increased resistance to the mercerising test (17·5% NaOH), viz., from 91·5 to 93·2.

The degree of purification of the cellulose, however, was still unsatisfactory.

A mixed process (*a*) with the aqueous acid, (*b*) with the neutral sulphite (Na_2SO_3), carried out as above but without washing the pulp, gave similar resu with no advance in the degree of purification of cellulose.

Series 63–70.—Observations were made to dete mine the influence of the degree of subdivision of t wood substance; *e.g.*, "mechanical wood pulp" (

round spruce), (2) graded saw dust, and (3) wood neal. In these forms the attack extended in a very iarked degree to the cellulose, without facilitating ie specific lignone reaction of sulphonation. The sults are of some theoretical importance in regard the constitution of the lignocellulose complex; the iarked change of reaction relationship to the acid etermined by mechanical subdivision is a new point f evidence of a physically constituted lignocellulose.

In regard to the practical purpose of a pulping rocess it is clear that the standard form of "chips" he optimum mechanical preparation of the wood. n the meantime a special digester of 1·8 cb. m. city constructed on the exact plan of the 7–15 ton sters . the mill had been installed. With ges 300 kg. of spruce chips the scale of operas ished a close comparison in regard to the and reaction in the digester, with the results ordinary mill process. In a series of operations, y followed by way of control analysis of blow-off es (liquor and pulp), the working advantages and tions of the process have been exactly defined.

important result of the change of condition the laboratory digester—of small capacity, lined, and with no circulation of the digestion r, was the small observed increase in the SO_4 uced. This was from the 0·0 (by treatment of liquors) to 1·0—1·3 g. per litre; whereas in the ratory process the increases, always a multiple e above, reached in some cases 8·5 g. per litre.

e actual mode of action of sulphuric acid involves mber of factors which require investigation; as the textbooks are satisfied with comprehenut loose descriptions of effects, ascribed to the out without such investigation (*supra*).

improvement in regard to this factor no doubt buted to the general improvement of the s as a pulping process, over the laboratory

improvement was confirmed by further operan the mill digesters of 7 tons capacity.

in the close study of the operations on the d scale we were able to define a point or phase marked a limit of reaction, and at the same time oduce a new factor of reaction, which has ined another and more favourable attack from

above brief outline of systematic research s by implication the logical steps of develop- the present position of controlled treatment process.

sults of the further investigations of the and the process in terms of products (cellu- lignone derivatives) are, however, reserved ater communication.

the pleasant duty of acknowledging the collaboration of Dr. B. Berbom, we would that he has been personally responsible for the us work of the programme of laboratory rch outlined in the paper.

e also acknowledge the efficient work of Mr. E. hrystall in the above, and in the investigations ded in the following paper.

The above researches planned in 1921 were started in February, 1922, and represent an important section of the plan of critical revision, for which the Latham Fellowship was instituted.

Since the Fellowship fell vacant in 1923, Mr. Hall was appointed, and as Dr. Dorée offered to associate himself with the research work, it was a favourable opportunity for extending the investigations of the constitution of lignocelluloses in which we have been associated (Cross and Dorée, "Researches on Cellulose," IV., 1922).

The work recorded in the following paper is a worthy fulfilment of the purpose of the Fellowship.

THE LIGNOSULPHONIC ACID OBTAINED BY THE ACTION OF SULPHUROUS ACID ON SPRUCE WOOD.

BY CHARLES DORÉE AND LESLIE HALL (*Latham Fellow*, 1923-24.)

In the ordinary bisulphite process the wood is resolved by the action of calcium bisulphite at 110° 150° the lignone appearing in solution as a calcium lignosulphonate, but it has hitherto not been considered possible to effect a satisfactory resolution with sulphurous acid alone unless a certain proportion of a base is present. In fact, it is generally held that the basic oxide (CaO, MgO, Na_2O) is the determining factor of the sulphonation reaction.

A process has, however, recently been developed under the patents of C. F. Cross and A. Engelstad (E.P. 12,943, 1922), in which spruce wood is heated with a 7% solution of sulphurous acid, previously freed from sulphuric acid, at 100°—110°, with satisfactory results. The patent relates chiefly to the specific characteristics of the by-product liquor and of its main constituent, which offer advantages in respect of technical industrial applications. The matter was prosecuted in these directions only after it had been established that the main reaction in the digestion process is a sulphonation of the lignone complex, a fact which is in opposition to the categorical statements of leading authorities.

The low temperature of the digestion (below 110°), and the apparent simplicity of this method of resolution, led us to hope that the free lignosulphonic acid thus obtained would afford a simple and less condensed material for an investigation into the nature and constitution of wood lignone than the complex by-product of the bisulphite processes upon which all previous work has been done. The results obtained are given in the present paper.

The new liquor, on preliminary investigation, was found to differ from calcium bisulphite liquor in its tanning qualities and in its capacity to form gels. It may be mentioned that in addition to the lignosulphonic acid, or its salts, both dextrinous and

sugar substances, organic acids and, in the case of the new liquor, considerable quantities of free sulphuric acid are present.

It might be argued, as has been done by Wislicenus (Koll.-Z., 1920, 27, 209), that the lignone constituent isolated from the lignocelluloses in this way, or by digestion with sodium hydroxide, as for example with the straw lignin of Beckmann, Liesche, and Lehmann (Z. angew. Chem., 1921, 34, 285), and the flax lignin of Powell and Whittaker (J. Chem. Soc., 1924, 125, 35) could not, considering the complexity of the plant substance, ever be homogeneous. In all these cases, however, a product has been obtained which, after such purification as is possible, passes through a series of chemical changes apparently as a definite compound. The composition of the various lignosulphonic acids obtained by different workers varies considerably, however, as shown in the following table.—

Table I.

	Composition of the sulphonic compound	Number of methoxyl groupings
Lindsay and Tollens, Annalen, 1892, **267**, 341.	$C_{26}H_{30}O_{12}S$	2
Seidel, Mitt. Techn. Gew. Mus., 1897, **7**, 119.	$C_{26}H_{30}O_{12}S$	2
Streeb, Diss., Gottingen, 1892	$C_{36}H_{48}O_{22}S_{2}Ba$ ..	3
Klason, Ark. Kem., Min. Geol., 1908, **3**, No. 5, 1	$C_{40}H_{44}O_{17}S_{2}Ba$.	ca. 1
	$C_{40}H_{44}O_{17}S_{2}Ba$ ..	ca. 4

	$C_{21}H_{20}O_{11}SNa$	
	$C_{21}H_{25}O_{11}SNa$	
Honig and Fuchs, Monatsh., 1918, **39**, 1.	$C_{45}H_{50}O_{18}S\ Ba$ ..	4
	$C_{40}H_{44}O_{17}S_{2}Ba$ ..	1
	$C_{74}H_{114}O_{49}S_{2}Ba$ ..	3
Konig, Cellulose-chem., 1921, **2**, 105. ..	$C_{36}H_{40}O_{22}S_{4}Ba$	

The usual methods of purification employed with calcium bisulphite liquors consist in fractional precipitation with sulphuric acid, or with salt solutions, fractionation of the barium salts, etc.

Taking advantage of the colloidal character of lignosulphonic acid, we employed for the preliminary purification of the sulphurous acid liquor and isolation of the main by-product, a prolonged dialysis whereby some 40% of the total solids present were removed and a lignosulphonic acid free from sulphuric acid, hexoses, and pentosans was obtained, completely water-soluble, if dried at 40° (see p. 260 T). The acid after fractionation had the unit formula $C_{26}H_{30}O_{12}S$, two methoxyl groupings being present. This C_{26} unit persisted throughout a series of transformations.

As will be seen from Table I., this composition agrees with the old formula of Lindsay and Tollens, but differs from the modern ones. The difference, however, lies chiefly in the lower percentage content of sulphur, viz., 5·5 as against approximately 7·3% (Klason). A portion of the sulphur in these acids is stated by Melander to be combined as sulphite ester. In accordance with this the purified acid used by us on reduction with zinc and hydrochloric acid yielded 7% of the total sulphur present as hydrogen sulphide. If this be taken as a measure of sulphite ester its amount is therefore not great.

Klason has stated (Ber., 1920, 53, [B], 1864) that the calcium bisulphite liquors contain sulphonates of an α-lignin $C_{20}H_{20}O_{6}$ (aldehyde) and a β-lignin $C_{19}H_{18}O_{7}$ (acid). Pine lignosulphonic acid was found to consist approximately of 60% of α- and 40% of the β-compound. These were separated by utilising the capacity of the α-lignin to form an insoluble compound with β-naphthylamine. In repeating this method of fractionation on a large scale with the acid $C_{26}H_{30}O_{12}S$, we found that at least 96% reacted as α-lignin, which is additional evidence of the homogeneity of the acid obtained by the new process, and points to some resemblance in properties to α-lignin. If the sulphonic derivative of $C_{20}H_{20}O_{6}$ be assumed to be $C_{20}H_{22}O_{9}S$, this formula would become, calculated on a C_{26} unit $C_{26}H_{29}O_{12}S_{1\cdot3}$ as compared with the $C_{26}H_{30}O_{12}S$ found by us.

We have thus to take into account Klason's constitutional formula for α-lignin, which is derived from the supposed condensation of two molecules of coniferyl aldehyde to a compound of the following structure:—

which it will be noted is of purely aromatic type.

In attempting further to connect the C_{26} acid with derivatives previously obtained, we recall the action of baryta water on the barium salt obtained from bisulphite liquor, studied by Honig and Fuchs (Monatsh., 1920, 41, 215). A number of new barium salts were formed which were insoluble in water, and of complicated composition, but in addition there was isolated one characteristic soluble barium salt possessing marked tanning qualities, the yields varying from 30 to 90% of the total. The atomic ratio of Ba to S in this salt was 1 : In repeating this experiment on the C_{26} acid we obtained a similar soluble barium salt, but the yield was only 11% and the atomic ratio Ba to S approximately 2 : 1 (see p. 261 T).

We may summarise the results obtained from examination of the reactions and derivatives of acid $C_{26}H_{30}O_{12}S$ described in the experimental in the following formula:—

$C_{21}H_{15}O_{2}(SO_{3}H)(OH)_{2}(CH_{2}OH)(CHOH)(CHO)($

The probable presence in the complex of the groups shown, enables the whole of the oxygen present be accounted for with the exception of two a which in the light of previous evidence may w present in a pyrone nucleus.

In the further investigation of the by-prod regard to constitution useful results were obt from a study of the action of dilute n Previous work has shown that lignin reacts wit nitric acid. Thus Oeman (E.P. 103,651, 1917) b oxidation of bisulphite liquors found that a substanc containing nitrogen was precipitated which could b used for dyestuff purposes. Powell and Whittake (J. Chem. Soc., 1924, 125, 359) state that flax ligni (isolated by means of caustic soda solution) whe treated with concentrated nitric and sulphuric acid at 0°, gave a nitro compound soluble in alcoho and acetone. Extensive oxidation took place eve at this temperature, the empirical change bein represented by the transformation of the ligni $C_{45}H_{48}O_{16}$, into $C_{42}H_{39}O_{22}N_{3}$. The original ligni

ntained four methoxyl and five hydroxyl group-gs, whereas the nitro compound contained three ethoxyl and six hydroxyl groupings.

Fischer and Schrader (Ges. Abh. Kennt. Kohle, 21, 6, 279), again, using 5N nitric acid and lignin lated by Willstatter's method, obtained a nitro mpound $C_{32}H_{37}O_{21}N_3$, containing 3 methoxyl groups, hydrogen atoms which could be titrated against kali, and 4 hydroxyl groups capable of acetylation. The dialysed acid $C_{26}H_{30}O_{12}S$ when heated on the ater bath with a 5% solution of nitric acid was gorously attacked, a clear red solution resulting. he sulphonic acid grouping was converted entirely to sulphuric acid. After dialysis to remove ineral acids the solution yielded an orange powder the composition $C_{26}H_{30}O_{18}N_2$ containing one ethoxyl grouping This substance was acidic, acting with barium carbonate to give a salt $_{26}H_{28}O_{18}N_2Ba$, and the presence of a carbonyl rouping was shown by its ability to condense with ne molecule of phenylhydrazine, although the action was to some extent abnormal in that three olecules of water were apparently eliminated:—

$$C_{26}H_{30}O_{18}N_2 + C_6H_5N_2H_3 = C_{32}H_{32}N_4O_{15} + 3H_2O$$

similar reaction, however, takes place between polyhydroxycaramelan $C_{21}H_{28}O_{10}(OH)_8$ (Dorée Cunningham, Chem. Soc. Trans., 1917, 111, 589) phenylhydrazine, three or more molecules of er being eliminated during the condensation.

he results of our experiments with this nitro pound, described later, enable us to infer to e extent the nature of the changes that have n place during the action of nitric acid:—

$$C_{21}H_{15}O_2\left\{\begin{array}{l}SO_3H\\(OH)_2\\CHOH\\CHO\\CH_2OH\\(OCH_3)_2\end{array}\right. \xrightarrow[\text{nitric acid}]{5\%} C_{22}H_{22}O_5\left\{\begin{array}{l}(NO_2)_2\\(OH)_3\\CO\\COOH\\COOH\\OCH_3\end{array}\right. \xrightarrow[\text{nitric acid}]{32\%} C_{20}H_{24}O_{12}\left\{\begin{array}{l}(NO_2)_2\\(COOH)_6\end{array}\right.$$

Lignosulphonic acid $C_{26}H_{30}O_{12}S$. II. Nitro compound $C_{26}H_{30}O_{18}N_2$. III. Nitro compound $C_{20}H_{30}O_{28}N_2$.

carbon grouping in the nitro compound (II.) nsider arises from the presence of a CHOH ing in the original lignin (I.), the aldehyde ng of which is oxidised to carboxyl. The carboxyl probably arises from a primary lic group The loss of a methoxyl grouping oxidation with nitric acid is difficult to n It may be due to the presence of the ing CH(OH)OMe which on oxidation would give formic acid with the loss of one atom of carbon. This loss apparently did not take place in the case of the nitro derivative. A similar change in the number of methoxyl groups in the complex was observed both by Fischer and Schrader and by Powell and Whittaker.

The special reactions of the nitro groupings present in the compound $C_{26}H_{30}O_{18}N_2$, given below, enable conclusions to be drawn as to their character and throw some light on the constitution of lignone itself:—

1. The compound gave a deep red colour with alkalis and on heating with these evolved ammonia, although only some 30% of the nitrogen present was actually obtained in this form.

2. On treatment with benzoyl chloride and alkali in the usual way a benzoyl derivative $C_{47}H_{44}O_{17}$ was obtained, the nitrogen atoms being removed in the process and two hydrogen atoms added:—

$$C_{26}H_{30}O_{18}N_2 \rightarrow C_{26}H_{29}(C_7H_5O)_3O_{14}.$$

3. On reduction with zinc and hydrochloric acid a nitrogen-free ketone $C_{25}H_{28}O_{17}$ was formed containing an additional carbonyl grouping for each nitrogen atom eliminated:—

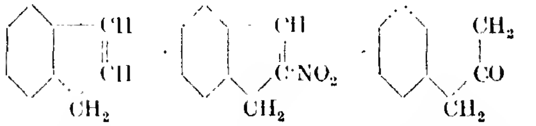
$$C_{25}H_{30}O_{13}(CO)(NO_2)_2 \rightarrow C_{23}H_{28}O_{11}(CO)_3.$$

A remarkable insoluble zinc compound was formed as an intermediate product in this reduction.

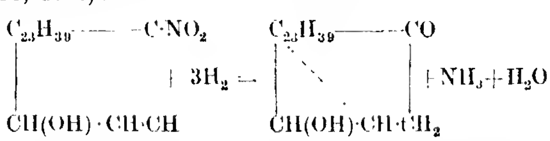
The ready nitration of lignin under the action of 32% nitric acid has led Fischer and Schrader to infer the presence of phenolic nuclei in the lignin complex, though no evidence is brought forward as to the aromatic character of the nitro groupings in the compounds obtained by them.

The properties of the nitro compound (II.) just described lend no support to the assumption of benzenoid rings in the lignin complex.

The reactions recall rather the observations of Wallach (Annalen, 1904, 336, 1; 1905, 340, 1, etc.), Pesci (Gazzetta, 1886, 16, 227), Wieland (Ber., 1903, 36, 2558), and others on the action of nitrous gases on unsaturated terpenes, whereby, by the elimination of nitrous acid, unsaturated nitro compounds are formed. These on reduction yield saturated ketones. Isosafrol, methyleugenol, α- and β-phellandrene, and indene, for example, behave in this way. Indene gives β-hydrindone thus:—



and the complex terpene cholesterol $C_{27}H_{46}O$ treated with concentrated nitric acid in the presence of glacial acetic acid gives a nitro compound which on reduction with zinc and acid passes to the saturated ketone dehydrocholestanonol (Windaus, Ber., 1903, 36, 3754):—



The resemblance disclosed by these observations to the nitrogen-containing substance from lignone

is striking and leads us to infer that the double linkings which are points of reactive activity in lignone are situated in reduced (hydroaromatic) rings.

The explanation we put forward of the changes observed is as follows:—Lignin as it exists in wood is a substance resembling in its properties the α-lignin $C_{20}H_{20}O_6$ of Klason. It is possible that the β-lignin, always found in the calcium bisulphite liquors, is a derived product formed from lignin during the cooking process. Its absence from the sulphurous acid liquors may be accounted for by the generally milder conditions employed in this process. The lignin complex

$$C_{21}H_{15}O_2(SO_3H)(OH)_2(CHOH)\cdot(CH_2OH)(CHO)\cdot(OMe)_2$$

contains in the nucleus hydroaromatic rings in one, or two, of which the two unsaturated linkages are situated. During cooking one of these is saturated by the sulphurous acid probably $-CH:CH-$ becoming $-CH_2\cdot CH(SO_3H)$. This conditions the removal of lignin as a lignosulphonic acid.

On oxidation by dilute nitric acid the sulphonic group is removed as sulphuric acid and at this linkage, and by a change similar to that observed with the unsaturated terpenes, the conversion from sulphonic acid to nitro-derivative and from this, by reduction, to a saturated ketone takes place as follows:—

$$\cdot C(SO_3H)\cdot CH_2\cdot \rightarrow \cdot C(NO_2):CH\cdot \rightarrow \cdot CO\cdot CH_2\cdot$$

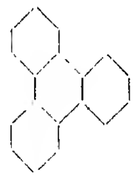
The lignosulphonic acid showed great stability when oxidised by more concentrated nitric acid. With acid of *d* 1·5 a violent reaction set in with the production of oxalic acid in fairly large amount. A considerable proportion of the organic matter present (some 20%), however, was converted into an acid (III.) $C_{26}H_{30}O_{28}N_2$. This product was obtained in better yield by using acid of 32% concentration (5*N*).

The survival of the C_{26} unit points to a great stability of the lignone complex, recalling that of the complex terpenes of the cholesterol series and may be held to support the argument for a complex hydroaromatic nucleus. Oxalic acid also is not uncommonly formed from hydroaromatic compounds on oxidation, as, for example, in the case of quercitol.

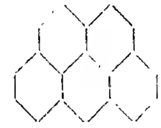
The remarkably high percentage of oxygen present in this nitro-acid makes it difficult to give any theory as to constitution. We have made many preparations of the substance, and also converted it from one salt to the acid and to other salts, but in every case the empirical composition remained unaltered, so that we can merely note this very unusual composition.

The reactions of this nitro-acid (III.) correspond to a formula $C_{20}H_{24}O_{12}(COOH)_6(NO_2)_2$. The nuclear C_{20}, together with the evidence just cited, recalls the constitution suggested for lignin (Z. angew. Chem., 1923, **36**, 149) by W. Schrauth, who regards it as based upon a reduced benzophenanthrene derivative $C_{18}H_{30}$ (IV.).

Schrauth demonstrates that by the condensation of three molecules of 5-hydroxymethylfurfuraldehyde a derivative of (IV.) containing two methoxy groupings could be formed. Two such units linking together give a C_{40} unit which is identical in composition with products isolated from lignin by Fischer, Klason, and others.



(IV.)



(V.)

Our results are in agreement with the general conclusion as to the presence of hydroaromatic ring systems in the lignone complex, of a stability recalling those of the complex terpenes of the cholesterol group; but the connecting oxygen atoms involved in Schrauth's formula do not make for stability, and we have been able to account for the oxygen atoms of the C_{26} unit acid in other ways. A ring system such as (V.) would be in better agreement with our results.

EXPERIMENTAL.

The material used in this research was the concentrated liquor from the process described in E.P. 12,943, 1922, containing therefore the lignone and other components of the non-cellulose of the coniferous wood. Analysis of a particular specimen gave the following figures: Total solids, 30·5; ash, 1·3; free sulphuric acid, 3·8%. The liquor possessed a slight odour of sulphur dioxide and furfural.

Comparison of the properties of the new product liquor with one from the calcium bisulphite process, each concentrated to 34% total solids:

	7% SO_2	Calcium bisulphite
1. Nature of the solids	Not hygroscopic	Not hygrosco.
2. Total solids left after dialysis (one day)	63·7% ..	64·2%
3. 10 g. liquor with 10 g. conc. hydrochloric acid	Ppt. at once ..	Ppt. after 5
4. 5 g. liquor with 10 g. glacial acetic acid	No ppt. ..	Completely
5. 10 g. liquor with 30 g. alcohol ..	No ppt. .	Completely
6. 10 g. liquor with 10 g. saturated brine	Thickened and pptd. after 15 minutes. ..	No change.

Isolation of the lignosulphonic acid, $C_{26}H_{30}O_1$

The liquor was diluted with water and subjected to dialysis in cellulose parchment bags for a week, during which time the whole of the sulphuric acid and the sugars were removed. The dialysed solution was then evaporated to dryness, the solids being kept below 50°: dried at higher temperatures °–10 they became insoluble in water. The acid formed a brown, non-deliquescent powder, freely soluble in water and alcohol-water mixtures, but insoluble in ether, in 96% alcohol, and in other organic solvents.

Specimens of the acid obtained by fractionation with ether from aqueous alcoholic solution gave on analysis*: C = 55·1, H = 5·5, S = 5·5, OMe = 11·3%.

* NOTE.—The analytical figures given in this paper are calculated on ash-free substance. It should be mentioned that the ash in many of the preparations was high, varying from 6% in the original purified acid to 1% in some of the derivatives. It consisted largely of silica derived from the lining of a new digester and was retained with great persistency through many chemical changes.

$C_{24}H_{24}SO_{10}(OMe)_2$ requires C = 55·1, H = 5·3, S = 5·6, OMe = 11·0%.

The acid gave 1·2% of furfuraldehyde on distillation with 12% hydrochloric acid.

Reduction of the lignosulphonic acid with zinc and acids.—A hot 10% solution of lignosulphonic acid was treated with zinc dust and dilute acid (acetic or hydrochloric) until the evolution of hydrogen sulphide had ceased. The solution was filtered, dialysed to remove salts, and then evaporated to dryness as described above. The product still contained 5·2% of sulphur, that is at most 7% of the combined sulphur was removed by this treatment.

The barium salt of lignosulphonic acid.—A 10% solution of lignosulphonic acid was boiled with excess of barium carbonate. After standing, the solution was decanted into a tall cylinder, the last traces of the carbonate allowed to deposit, and the barium salt precipitated in four fractions by means of alcohol. Each fraction was dried at 100° before analysis. The following results were obtained :—

Fraction.	Yield, %.	S, %.	Ba, %.
1	63	4·8	7·7
2	13	4·9	8·1
3	13	5·1	7·0
4	3	5·2	4·7
Calc. for $C_{42}H_{46}S_2O_{24}Ba$,		S = 5·1	Ba = 10·9

he residual liquid on evaporation to dryness gave rther quantity of a light brownish-yellow powder, aining barium, very soluble in water and alcohol önig and Fuchs (Monatsh., 1920, **41**, 215) treated lution of the barium salt of lignosulphonic acid the bisulphite process with baryta water and ined a very characteristic soluble barium salt to h they gave the formula $C_{18}H_{30}O_{10}SBa$.

n repeating the preparation using 50 g. of the 5·4 g. of soluble barium salt were obtained, h, as regards qualitative tests, resembled the aration of Hönig and Fuchs, but analysis gave 23·9, S = 2·9%, whence Ba : S = 1·92, whereas g and Fuchs found for three different preparations Ba : S = 0·97, 0·89, and 0·87.

β-naphthylamine compound of the lignosulphonic Klason (Ber., 1920, **53**, [B], 706) found that solution of calcium lignosulphonate is treated ne of β-naphthylamine hydrochloride a conion product is precipitated to which he ascribed rmula

$$C_{18}H_{19}O_5\cdot CH\begin{cases} SO_2\cdot O \\ \quad\quad | \\ CH \quad NHC_{10}H_7 \end{cases}.$$

g the acid C_{26}, an almost quantitative yield of a pound was obtained, containing S = 4·6, N 1%, $C_{26}H_{30}SO_{12}.C_{10}H_9N$ requires S = 4·5, N = 2·0; $C_{26}H_{30}SO_{12}.C_{10}H_9N - H_2O$ requires S = 4·6, N = 2·0. It was decomposed by caustic alkalis and by yridine with the liberation of β-naphthylamine, and ppears therefore to be a simple salt (*cf.* Hintikka, ellulosechem., 1923, **4**, 93).

The benzoate of the lignosulphonic acid.—5 g. of gnosulphonic acid were dissolved in 80 c.c. of 10% odium hydroxide solution and treated with 18 g. of enzoyl chloride in the usual way. The reaction roduct was poured into water, and the solid which parated, after washing, was dried in a vacuum at 40°. The benzoate formed a light brown powder, insoluble in water and alcohol and slightly soluble in pyridine. The result of the analysis agreed with the presence of three or four hydroxyl groups. Found C = 65·0, H = 5·6, S = 3·0%. $C_{26}H_{27}SO_{12}.3(C_7H_5O)$ requires C = 64·7, H = 4·8, S = 3·6%. $C_{26}H_{26}SO_{12}.4(C_7H_5O)$ requires C = 66·0, H = 4·7, S = 3·3%.

Attempts to prepare the corresponding acetate were unsuccessful, since sulphur dioxide was evolved in some quantity on treatment of the lignosulphonic acid with acetylating agents.

The bromine derivative of the lignosulphonic acid.—10 g. were dissolved in a mixture of 20 c.c. of water and 60 c.c. of glacial acetic acid. An excess of bromine in acetic acid was then added with cooling. Some hydrobromic acid was evolved. The product was poured into ether, the light yellowish precipitate washed with ether to remove acetic acid and then dried in a vacuum at the ordinary temperature. Found S = 3·6, Br = 26·7%, Br/S = 2·9. $C_{26}H_{29}SO_{12}Br_3$ requires S = 4·0, Br = 29·8%.

The phenylhydrazine derivative of the lignosulphonic acid $C_{26}H_{30}O_{11}S(N_2H\cdot C_6H_5)$. 5 g. of lignosulphonic acid dissolved in 30 c.c. of water were added to a solution containing 5 g. of phenylhydrazine, 2·5 g. of acetic acid, and 6·5 g. of sodium acetate in 30 c.c. of water. An abundant red-brown precipitate was formed at once, which after standing was filtered off, washed, and dried in a vacuum. Found C = 59·1, H = 5·9, N = 4·3, S = 4·5%. $C_{32}H_{36}O_{11}N_2S$ requires C = 58·5, H = 5·5, N = 4·3, S = 4·9%.

The presence of one reactive carbonyl group per 26 carbon atoms thus indicated was approximately confirmed by oxidation of the acid with Fehling's solution. 0·2913 g. of acid gave 0·1000 g. of cupric oxide; whence CHO = 6·3%. $C_{25}H_{29}SO_{11}CHO$ requires CHO = 5·1%.

The action of oxidising agents on lignosulphonic acid. (i) *Nitric acid (5% concentration). Nitro compound A.* $C_{25}H_{27}N_2O_{17}(OCH_3)$.

One part of lignosulphonic acid was heated on the water bath with 20 parts of 5% nitric acid. After a few minutes a vigorous reaction set in with foaming. The heating was continued for four hours, after which the bright red liquid was dialysed for one day to remove the sulphuric acid formed, and excess of nitric acid. On evaporation a light orange non-deliquescent powder remained. Yield 60% of the original acid. The compound was very soluble in water, but insoluble in pure organic solvents. With dilute aqueous alkalis it gave a deep red solution, which on warming evolved ammonia in some quantity.

For analysis it was dried at 50° in a vacuum. Found C = 47·4, H = 4·6, N = 4·2, OMe = 4·4%. $C_{25}H_{27}N_2O_{17}(OCH_3)$ requires C = 47·4, H = 4·6, N = 4·3, OMe = 4·7%.

This nitro compound dialysed much more rapidly than the original acid. It was completely precipitated from solution by gelatin and gave reddish-brown precipitates with salts of the heavy metals and the alkaloids. It was also precipitated from aqueous solution by the addition of excess of a mineral acid.

Journal of the Society of Chemical Industry.

The barium salt, which is soluble in water, was prepared as follows: A solution of 1·4 g. of the nitro compound A in 20 c.c. of water was heated on the water bath with excess of barium carbonate. No ammonia was evolved. The filtrate containing the barium salt was precipitated by alcohol and the brownish-red precipitate dried at 100°. Found Ba 17·9%. $C_{26}H_{28}N_2O_{18}Ba$ requires Ba 17·3%.

When a solution of this barium salt was treated with baryta water, a light brown precipitate was formed, and on heating on the water bath, ammonia was slowly evolved. The precipitate was readily soluble in acids.

Distillation of the nitro compound A with caustic soda solution.—A weighed quantity of the compound was distilled with $N/2$ sodium hydroxide solution, the distillate being collected in standard acid. The result indicated that 29% of the nitrogen present was evolved in the form of ammonia.

Phenylhydrazine derivative, $C_{32}H_{32}N_4O_{15}$. This substance was prepared as in the case of the corresponding derivative of lignosulphonic acid. It formed a dark red powder insoluble in water and alcohol. Found C 53·9, H 5·3, N 8·1%. $C_{32}H_{32}N_4O_{15}$ requires C = 53·9, H = 4·5, N 7·9% i.e., $C_{26}H_{30}N_2O_{18}$ + $C_6H_5NH.NH_2$ = $C_{32}H_{32}N_4O_{15}$ + $3H_2O$.

Benzoylation of the nitro compound A.—The nitro compound was treated with benzoyl chloride and caustic soda in the usual way. The product formed a yellowish-white powder, insoluble in solvents, and was nitrogen free. On heating it softened at 80°, but did not show any definite melting point. The analysis points to a tribenzoyl derivative.

Found C = 64·4, H 5·5%. $C_{47}H_{44}O_{17}$ requires C = 64·1, H 5·0%.

These figures indicate a substitution of 3 hydrogen atoms by benzoyl groupings accompanied by loss of N_2O_4 and probable addition of 2 hydrogen atoms in their place.

$$C_{26}H_{30}O_{18}N_2 \longrightarrow C_{26}H_{29}O_{14}(C_7H_5O)_3 + N_2O_4.$$

Reduction of the nitro compound A.—A solution of the compound acidified with hydrochloric acid was treated with zinc dust and the mixture heated on a water bath. A dark brown precipitate rapidly formed and the reduction was allowed to continue until no further precipitate was formed. The liquid, together with the precipitate, was then poured off from the excess of zinc into a tall cylinder and the precipitate washed with acidified water by decantation until the washings were colourless. The residue (which was found to contain 26% of zinc), was dissolved in $N/2$ caustic soda and made acid with hydrochloric acid. The voluminous precipitate produced was filtered off, washed, dried at 50° and finally in a vacuum. In this way, the reduction product was obtained as a dark brown powder free from nitrogen and zinc, insoluble in water, acids, and organic solvents, but readily soluble in alkalis and sodium bisulphite to a red solution.

Found C = 50·5, H 4·6%. $C_{26}H_{28}O_{17}$ requires C = 50·9, H = 4·6%.

Preparation of phenylhydrazine derivative of above reduced compound.—In order to prepare the phenylhydrazine derivative from this compound, 2·3 g. were dissolved in a 5% solution of sodium bisulphite, and to the resultant solution 4 g. of phenylhydrazine and 5 g. of sodium acetate dissolved in 60 c.c. of 20% acetic acid were added. After standing, the red-brown precipitate was filtered off, washed with dilute acetic acid and then with water, and then dried first on a plate and finally in a vacuum. The phenylhydrazone (wt. 1·25 g.) contained only a trace of sulphur.

Found N = 9·5%. Calc. for $C_{41}H_{46}O_{14}N_6$, N = 9·5%.

(ii) *The action of 32% nitric acid on lignosulphonic acid. Isolation of an acid* $C_{20}H_{24}N_2O_{16}(COOH)_6$.

When 40 g. of lignosulphonic acid were treated with 200 c.c. of 32% nitric acid, the mixture became warm and nitrous gases were evolved with foaming. After heating for two hours on the water bath the excess of nitric acid was removed by repeated evaporation with water. On cooling, the red liquid was separated from crystals of oxalic acid which had formed and neutralised with barium carbonate. The filtrate (230 c.c.) contained the soluble barium salt, which was separated into four fractions.

Fraction 1 was deposited on allowing the solution to stand. Fractions 2 and 3 were obtained by the successive addition of 20 and 60 c.c. of alcohol. Fraction 4 consisted of the residue obtained by evaporating the final filtrate to dryness.

These fractions were dried in a vacuum and analysis gave the following figures:—

Fraction.	Yield, g.	Found. N, %.	Found. Ba, %.
1	3 3	2 12	34 7
2	3 8	2 10	31 3
3	4·7	2 03	30 6
4	4 8	—	25 1

Fraction 2 gave on analysis C = 25·3, H = 2·[illegible] Calc. for $C_{26}H_{24}N_2O_{28}Ba_3$, C = 25·5, H = 2·0, N = 2·3, Ba = 33·6%.

The reactions of the barium salt fraction 2 were as follows:—

1. With solutions of lead, iron, mercurous, [illegible] brucine, and β-naphthylamine salts yellowish-[illegible] precipitates were obtained.
2. Warmed with caustic soda, ammonia evolved.
3. On treatment with zinc and hydrochloric [illegible] the red colour of the solution changed to y[illegible] but on boiling and allowing the product to stand reverted to the original colour.
4. On fusion with caustic potash oxalic acid [illegible] produced in some quantity, but no evidence for production of aromatic compounds could be obtained.
5. A cold alkaline solution of potassium permanganate effected complete oxidation to oxalic acid.

Preparation of the free nitro-acid $C_{26}H_{30}N_2O_{28}$.—The barium salt was dissolved in water and treated with the calculated quantity of sulphuric acid and the filtrate evaporated to dryness. The product formed a dark red, very deliquescent powder, which was dried at 40° and in a vacuum. Found C = 38·3, H = 3·7%. Calc. for $C_{26}H_{30}N_2O_{28}$, C = 38·1, H = 3·6%.

The lead salt was prepared from the free acid by the addition of lead acetate acidified with acetic acid.

he light brown precipitate was dried at 95°. It was nly slightly soluble in water or acetic acid. Found Pb = 47·5%. Calc. for $C_{26}H_{24}N_2O_{28}Pb_3$, Pb = 44·1%.

The action of alkaline potassium permanganate nd ozone on lignosulphonic acid under a variety of onditions led only to the production of oxalic acid nd formic acid respectively, no evidence of the ormation of more complex compounds being obained.

We are indebted to Mr. E. R. Chrystall for the llowing results of experiments with chromic acid.

Analysis of sample of liquor employed.—Total lids, 32·8; free sulphuric acid, 4·6; total sulphur, 35; ash, 1·0%.

Four samples of the above liquor were treated with olution of chromic acid equal to 15, 30, 45, and 0% of the lignone solids, diluted so that the final soluion contained 10% of lignone solids. The solutions re kept for two days. The 15% solution remained uid. The 30 and 45% solutions were gelatinous one day and the 60% in two days. The lignone lloid was then dissolved in caustic soda and rated with Fehling's solution.

The same oxidised products were treated with a tion of phenylhydrazine acetate and the products mined.

he hydrazine solution reacted readily in the cold the gelatinised lignone colloid, and after stirring standing overnight became entirely transformed a red-brown powder which could be readily red and washed. It was weighed on a tared and dried at 100°. The hydrazone from the sed lignone did not fuse at this temperature as the corresponding derivative of the untreated ne. The results are recorded in the table given w:—

Solution.	Glucose equivalent of lignone solids. %	Hydrazone % on lignone solids. %	% Cr_2O_3 in the ash.
liquor	86·5	56·3	—
	84·3	98·4	7·7
	61·5	111·0	9·0
	52·0	118·4	13·4
	47·5	144·8	18·4

results are in agreement with those obtained action of nitric acid. The fact that the ty to reduce Fehling's solution steadily falls ncreasing oxidation by chromic acid indicates he aldehydic grouping is being converted to yl, whilst the marked increase in the yield of one confirms the development* of carboxy ngs at first by simple oxidation of a CH(OH) ng, but later probably by the opening up of systems and the production of new points of activity.

Summary and conclusions.

Aqueous sulphurous acid is able to resolve the ferous wood substance giving as the chief nonulosic product a lignosulphonic acid, $C_{26}H_{30}O_{12}S$.

2. This acid differs from those previously obtained from the calcium bisulphite process in containing a lower proportion of sulphur, 5·5 against 7·3%. It shows, however, a general resemblance in properties, *e.g.*, in its reactions with baryta, but the products, though of a similar type, are specifically different.

3. The acid was purified by prolonged dialysis of the by-product liquor and on fractionation by β-naphthylamine, behaved as a homogeneous substance resembling the α-lignosulphonic acid of Klason.

4. A study of the reactions of the acid $C_{26}H_{30}O_{12}S$ has led to the dissected formula $C_{21}H_{19}O_2(SO_3H)(OH)_2(CH_2OH)(CHOH)(CHO)(OCH_3)_2$, in which all the oxygen atoms but two are accounted for.

5. The action of dilute (5%) nitric acid leads (*a*) to the removal of the sulphonic group as sulphuric acid, (*b*) to oxidation of the CH_2OH and the CHO groupings to carboxyl, while the CHOH grouping becomes CO; (*c*) at the same time nitration takes place, resulting in the formation of a nitro compound $C_{26}H_{30}O_{18}N_2$.

6. The reactions of the nitro groups differ entirely from those of, for example, the nitrophenols. Thus on treatment with alkali the nitrogen is removed as ammonia, and on reduction also ammonia is produced and a nitrogen-free ketone $C_{26}H_{28}O_{17}$ is formed, containing three carbonyl groupings, each nitro group having been replaced by carbonyl.

This reaction is well known among the unsaturated terpenes, nitration taking place at the unsaturated linking.

7. Further oxidation with fuming nitric acid or better with acid of 32% concentration, gives oxalic acid, and an acid $C_{26}H_{30}O_{28}N_2$ shown by experiment to be $C_{20}H_{24}O_{12}(COOH)_6(NO_2)_2$.

8. The persistence of the C_{26} unit through all these changes with a resistant nuclear unit of the order of C_{20} leads us to the conclusion that the nucleus of lignone is hydroaromatic in character, consisting of a complex of reduced rings somewhat resembling the reduced benzophenanthrene hydrocarbon obtained by Schrauth (*loc. cit.*). This theory involves the general absence of oxygen linkings, the attachment of the side groups, including the CHO grouping, directly to the carbons of the ring, and the presence of double linkings in the reduced ring, for which evidence has been obtained.

One of us (L. H.) desires to thank the Council of the Society of Chemical Industry and Sir Thomas Latham for his selection as Latham Research Fellow, and for the opportunity of carrying out the above investigation.

THE MODE OF RETENTION OF NITROGEN IN ELECTRIC ARC WELD METAL.

BY E. J. B. WILLEY, M.Sc.

It has long been known[1] that nitrogenised irons and steels show a decided decrease in ductility, accompanied by a corresponding increase in hardness and tenacity as compared with the normal products of everyday use. Andrew[2] has shown that the

[1] Beilby and Henderson, Chem. Soc. Trans., 1901, **79**, 1250. Braune, Rev. Mét., 1905, **2**, 497.
[2] J. Iron and Steel Inst., 1912, **2**, 210; see also Colver-Glauert, Memoir to Commissioners of the 1851 Exhibition, 1908.

presence of 0·25% of nitrogen causes a total suppression of the critical changes which occur in normal steels, and a profound modification of the mechanical properties of the metal follows as a result of the carbides being kept in solution. As Tschichevski[3] has pointed out, by analogy with phosphorus, nitrogen may be expected to exert some of the deleterious influences so characteristic of the cause of "cold-shortening" etc.

Fortunately the quantity of nitrogen present in irons and steels is usually so small as to be without any apparent effect on the metal, but where it is present in considerable amount it becomes a source of great trouble and is difficult to remove (*cf.* Andrew, *loc. cit.*). The nitrogen, which is invariably found in all welds made by the electric arc process, is believed to be the principal cause, along with oxygen, of the somewhat undesirable characteristics (the brittleness in particular) of the metal thus produced, which have limited greatly the application of an otherwise useful and simple welding process.

Consequently an investigation into the chemistry and physics of the reactions between nitrogen and iron in the electric welding process is likely to provide information of considerable value, both to the pure chemist and to the welder, who is faced with the problem of devising a denitrogeniser for use under ordinary industrial conditions.

The salient facts relating to the combination of nitrogen and iron may first be stated.

(1) Three compounds of nitrogen and iron are known, namely (*a*) ferrous nitride, Fe_4N_2, which was first investigated by Stahlschmidt[4] and more fully by Fowler[5]; (*b*) two compounds of the formulæ Fe_3N_2 and FeN, which are presumably triferrous and triferric substituted ammonias and were obtained by Guntz.[6]

(2) None of these compounds has hitherto been obtained by direct union of the elements in question, and indirect means have always been found necessary. The two compounds prepared by Guntz are very unstable and it does not appear to the author that they need be considered for the purposes of this investigation.

The presence of nitrogen in weld metal, as well as the comparative constancy of the content, is very interesting in view of the facts expressed above, and it is obvious that the conditions are of a somewhat novel nature in view of this circumstance. Andrew, by prolonged heating of iron in nitrogen under great pressure, succeeded in preparing alloys containing 0·30% of the element, but his experimental conditions are obviously not comparable with those obtaining in welding practice. It is difficult to conceive of the nitrogen being in solution in the iron, since Jurisch[7] has shown that the gas is only slightly soluble in iron and that the solubility is proportional to the square root of the gas pressure. Hence it would appear that the nitrogen must definitely be combined with t[he] iron, either as a nitride (in solid solution), or el[se] in some system comprising iron, nitrogen, and oth[er] elements.

Paterson and Blair[8] have published some figur[es] for the nitrogen and oxygen contents of weld metal and they suggest that the nitrogen may be prese[nt] as a result of the exposure of the iron, while molte[n,] to active nitrogen produced by the arc. Von Lepe[l] seems to have had an idea that electrical influence[s,] apart from purely thermal considerations, play [an] extremely important part in the oxidation of nitrog[en] to nitric oxide by the well-known arc process, but [his] views were ignored until the researches of Haber a[nd] his school became recognised. Haber and Koenig working with high-tension alternating-current arc[s,] and Morden,[11] Holwech,[12] and Holwech and Koenig using short direct-current arcs, advanced mu[ch] experimental evidence in favour of the view that [an] active form of nitrogen is formed by passing the g[as] through an arc, and Lowry[14] showed that measurab[le] quantities of oxides of nitrogen were obtained [by] passing nitrogen through an ozoniser and mixing t[he] gas as rapidly as possible with oxygen. The la[st] named advanced much evidence in support of t[he] view that active forms both of nitrogen and oxygen, differing respectively from Strutt's w[ell] known form[15] and ozone, are obtained by the act[ion] of the electric discharge upon the gases in questi[on.] It is to be noticed that Strutt[16] has also obtai[ned] active nitrogen at ordinary pressures.

According to Strutt[16] the production of ac[tive] nitrogen is a function rather of the current den[sity] than of the voltage, and in welding practice the c[on]ditions for its formation may to a certain extent [be] regarded as favourable when the diameter of [the] welding electrode ($\frac{1}{8}$ in. or so) and the cur[rent] conditions (40–50 volts and 100 ampères and o[ver)] are considered.

It does not appear to the author that Pat[erson] and Blair's view (*loc. cit.*) that the nitrogen in [the] metal may be due to the effects of the active gas [on] the molten metal, is likely to be realised whe[n one] considers the effects of the hot metal upon the a[tmos]phere in its vicinity. Convection currents, ow[ing to] the intense heat of the arc and the fluid weld [metal,] will be very pronounced and will tend to carry t[he] gases (which presumably will contain the activat[ed] nitrogen) upwards and away from the metal surfaces, and the transformation of the active vari[ety] to ordinary nitrogen will be very rapid. Probabl[y a] considerable proportion of the activated oxygen a[nd] nitrogen will combine to form oxides of nitrog[en] which, being comparatively stable, may be carri[ed] round again to the surface of the metal and there a[ct] upon it.

üller and Barek[17] have, however, shown that e oxide is decomposed upon contact with heated ıls, but whether or not the same would apply itrogen peroxide (to which the nitric oxide from the would be oxidised by the air away from the arc f) they do not state.

ı the present research the author has endeavoured eal with the problem by investigating the pro-s obtained when an iron arc is burned in atmos-es of nitrogen and of air. It appeared very able from the outset that iron nitride might be ed in quite appreciable quantities when an iron s burned in nitrogen. The outer zone of the arc e, which consists (in the case of first-class rodes) largely of metallic vapours, would be in act with active nitrogen produced by the arc. se, together with the minute particles of iron tered from the electrodes, might react to give nitride, as stated above. Futhermore, the ection currents would tend to carry the products y from the actual arc zone, thus preventing mposition. This hypothesis was tested in the wing experiments (Fig. 1).

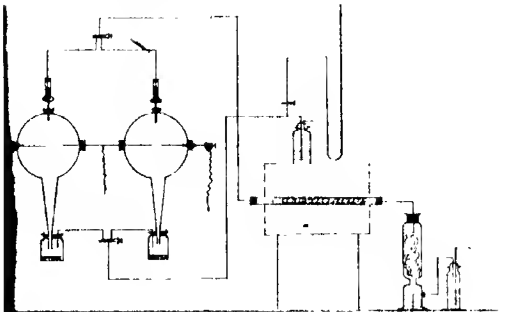

FIG. 1.

rogen from a cylinder was passed through sulphuric acid, up a soda lime-calcium chloride tower, through a furnace which could be d to bright redness and which was packed with lic copper, the stoppers being protected from ng by using a long tube (6ft.) and shielding well asbestos, then *via* the two-way tap to the large way 1500-c.c. bulbs. Small tubes packed with wool were placed on the uppermost tubulures he bulbs to prevent the possibility of small icles of iron being carried up into the gas stream. electrodes were placed horizontally as shown, consisted of No. 8 S.W.G. Armco iron wire 8% Fe). Attached to the long limbs of the s were two bottles containing sand to receive large pieces of iron which fell away by reason he electrodes melting, and the gas was then led y by means of the two-way tap to a Dreschel le containing strong sulphuric acid and thence to osphere. A manometer was also fitted as shown. electrodes were placed in parallel and arranged at the electrode unit had in series a steadying ance, the whole being connected *via* a high-on switch (voltmeter and ammeter leads were taken off appropriately) to the 220-volt D.C. supply. In this way the two arcs could be run in turn, one bulb cooling down while the other was burning, the two-way tap permitting of the necessary diversion of the gas stream. One electrode in each bulb was fixed rigidly by means of a rubber stopper, whilst the other passed through a piece of pressure tubing which fitted tightly into a larger hole in a rubber stopper passed through the tubulure. In this way a gland was obtained which was capable of withstanding pressure up to 9 in mercury and yet permitting of easy manipulation of the iron rod. Ebonite knobs were screwed to the ends of the movable electrodes and terminals sunk in these were attached the leads. The arc could thus be regulated to any desired length. In use, the apparatus was first filled with nitrogen and the gas stream run until no appreciable amounts of oxygen could be found in the issuing gas when examined by the Haldane apparatus. (Oxygen was the chief impurity to be guarded against, as it was particularly desired to secure its absence.) One of the arcs was then struck and allowed to burn in the nitrogen until the bulb became too hot to permit of its being touched by the hand, which usually took about five to seven minutes. This arc was then broken and the second one struck, the taps being turned to direct the gas stream as desired. In the first series of experiments no appreciable rise of pressure was allowed to occur in the apparatus.

The arcs burned well for some time, clouds of fine particles, resembling the motes in a sunbeam, being carried upwards and round to the sides of the bulb adjacent to the electrodes and away from the arc, finally settling on the bulb walls.

No appreciable quantities were carried out in the issuing gas, since only a faint reaction for iron was obtained from the sulphuric acid in the Dreschel bottle even after the arcs had been run for a considerable period. After the electrodes had been in use for about an hour or so they ceased to function well and the arc commenced to hiss and much spluttering took place. When this occurred the experiment was stopped and the electrodes were replaced by fresh ones.

It was found that a steady and satisfactory arc could be obtained by adjusting the resistance and arc length to give a P.D. of about 38—40 volts at the electrode ends and using a current of about 5 amps.

After a sufficient quantity of the deposit had accumulated the apparatus was opened up and the black material from inside brushed out into a weighing bottle, the nitrogen content being subsequently determined by the method described by Hurum and Fay.[18] This in reality differs little from the method advocated by Paterson and Blair (*loc. cit*) for the determination of nitrogen in weld metal, but the excess of acid is determined iodometrically. This obviates the necessity of using methyl orange or methyl red as indicator, both of these being unsatisfactory with dilute solutions such as are employed

anorg. Chem., 1923, **129**, 300.

[18] Chem. and Met. Eng., 1922, **26**, 218.

(*i e.*, $N/20$ acid, $N/50$ alkali or sodium thiosulphate). Prior to the actual analytical work connected with these experiments, a large number of blank determinations were carried out to ascertain what allowance was necessary for the traces of alkali etc. which inevitably pass over into the distillate etc., and Armco iron which had previously been heated to bright redness in a stream of pure hydrogen was employed as the standard metal with which to work. This might reasonably be supposed to be free from nitrogen.

In addition to this, the method was tested thoroughly against ammonium salts and other nitrogen compounds in which the nitrogen can be determined by Kjeldahl's method, and fresh blank determinations were carried out for every new supply of the reagents used.

The black substance collected from the bulb walls was found to contain 0·24% of nitrogen in the first experiments, 0·27% in the second, and 0·25% in the third series. This is very interesting as showing that some absorption of nitrogen by the arc vapours etc. does take place, and steps were forthwith taken to ascertain, as far as was possible, the precise nature of the nitrogen-bearing substance. If the nitrogen be chemically combined with the iron it is difficult to conceive of its being anything but a nitride, but there is always the possibility of its being adsorbed upon the very finely divided deposit.

Upon the substance being boiled for two hours with water in the distillation apparatus, a trace of ammonia only could be detected in the distillate, and upon dissolving the material in the flask and determining the nitrogen as usual, no alteration of the content of this element was found. With alkali in the distillation flask some ammonia was evolved equivalent to 0·064% of nitrogen, and the residual material still contained some nitrogen (0·172%), the sum of the two figures equalling the original value for the nitrogen content (0·236%, found previously 0·24%). Prolonged boiling resulted in the whole of the nitrogen being evolved as ammonia.

When the substance was heated to dull redness for 90 minutes in pure hydrogen, the issuing gases being bubbled through absorption bottles containing a known amount of standard acid, nitrogen amounting to 0·164% was evolved as ammonia, as was shown upon titrating back the acid, and the residual material contained 0·075% nitrogen; since the sum of these two figures equals (within the limits of experimental error) the original figure for the sample used (0·24%), it is to be concluded that no loss of nitrogen as such took place. The whole of the nitrogen was evolved as ammonia upon more prolonged heating.

Upon heating a quantity of the substance under identical conditions in a current of nitrogen, the whole of the nitrogen in the sample was given off, none being found upon analysis of the residue.

These facts are all in accordance with the view t the substance in question consists of a mixture 2% of iron nitride and about 98% of iron. Attem to separate any nitride by means of a magnet fail as did similar efforts based upon the insolubility iron nitride in nitric acid mentioned by Fow (*loc. cit.*). His statement is rather difficult to und stand, since it is the reverse of what would be pected, but he qualifies it by mentioning that concentration of the acid appears to be the m factor to be considered. The quantity of substa available did not permit of elutriation experime being performed.

Further experiments in this direction, are, howev in progress.

The electrodes used in these experiments w examined for nitrogen, but only 0·004 % was fou as the mean of several concordant analyses.

The tips between which the arc had burned w found to contain 0·050% N in one case and 0·06 in another, no difference in the nitrogen conte being detectable between the anode and catho In practice, however, it is very difficult to dec where the "tip" ends and the rest of the electr begins, and this may mask a possible differenc the nitrogen contents of the anode and cathode respectively The presence of nitrogen in the products thus having been established, it was thou that an equilibrium of sorts comprising the sys iron nitrogen-iron nitride might exist in vicinity of the arc, bearing in mind the somew remarkable constancy of the nitrogen conten the product obtained. If this be so, since the mation of the nitride will obviously be accomp by a decrease in the volume of the nitrogen pre an increase in the pressure of the gas should dis the position of equilibrium to a second point co ponding with an increased yield of nitride, acco to Le Chatelier's theorem of mobile equilib Strict equilibrium of the type obtained in classical reactions as the hydrolysis of ethyl ac could not be expected on account of the elect influences present,[19] but the matter was thou worthy of investigation.

Two more series of experiments were there carried out in which the pressure of nitrogen in apparatus was allowed to rise to 4½ and 9 in. mercury respectively, the other experimental det being as before. 0·27% of nitrogen was found the resulting products, thus showing that the incre of pressure does not greatly affect the arc conditi and that the equilibrium is not very sensit This is rather to be anticipated for the reas given above, *i e.*, that true chemical equilibrium hardly to be expected in the cases where electr influences play an important part, and also in v of the comparatively slight pressure employe

E MODE OF RETENTION OF NITROGEN IN ELECTRIC ARC WELD METAL.

BY E. J. B. WILLEY, M.Sc.

(*Concluded from p.* 266 T.)

ince the foregoing experiments favour the view t activation of the nitrogen is capable of bringing ut chemical combination of the gas and the iron, as thought that pre-activation might conceivably l to greater yields of the nitride, and this accord- ly was put to the test. The purified nitrogen s led by means of the two-way taps to Siemens nisers, approximately 22 cm. in length and placed parallel in the secondary circuit of a spark coil ig a current of 7000 volts and 0·07 amp. The isers communicated directly with the reaction s, since Lowry (*loc. cit.*) has shown that the e nitrogen obtained in this way is unstable in the course of a few seconds reverts to the nary form. For use, the apparatus was filled nitrogen as before and the coil was started. igorous discharge was obtained in the ozonisers the arcs burned well when struck.

he product in the bulbs was collected and nined as before, proving to contain 0·24% of ogen. This would indicate that the activation no effect upon the reactivity of the gas under circumstances of the experiment, and is probably to the extreme rapidity with which the active will be produced by the arc. The transition n the inactive to the active form will be nearly antaneous and hence pre-formation of the latter ety would not be expected to have much effect n the amount finally present. The author is bted to Prof. Briscoe for pointing this out to . The next series of experiments was devoted study of the action, if any, of nitrogen which been activated by passing it through the ozoniser n metallic iron heated to various temperatures. activated gas was led direct to the electric stance furnace which contained a small silica t carrying fine Swedish iron wire which had viously been carefully cleaned by washing with er, then with distilled water, and drying it at ° in the steam oven. The temperatures employed re that of the laboratory and 500° approximately. g. samples were used and the duration of the riments was two hours in each case.

he choice of 500° as the furnace temperature made from the following considerations:—

) The formation of iron nitride has been shown by Fowler (*loc. cit.*) to be a slightly exothermic reaction. Hence in accordance with general principles it may be expected to take place better at lower rather than at higher temperatures.

i) On account of the thermal decomposition of iron nitride mentioned by Fowler, too high a furnace temperature must again be avoided.

(iii) Since chemical reactions tend to increase in velocity with the temperature, too low a temperature must be avoided in this case if there is to be appreciable combination of the elements in question.

(iv) Since activated nitrogen appears to suffer catalytic reversion to the inactive form under the influence of hot surfaces, this must as far as possible be minimised by the use of a moderate temperature.

Hence 500° was chosen as an average temperature at which to work, and it would appear that some indication as to combination or otherwise of the iron and nitrogen should be obtained in a two-hour experiment.

Upon analysis, minute traces of nitrogen only were found and the controls employed (the ozoniser not being run for these, all other things being kept equal) gave the same results. Hence it would appear that activated nitrogen does not combine with iron when the latter is simply heated in the gas in question.

It is necessary, however, to take into consideration the possibility of much reversion of the active gas to the inert taking place owing to the catalytic action of the hot walls of the furnace tube. There is also to be considered the effect of passing the activated gas in its peculiar physical state into the intense magnetic field of the heating coil of the furnace.

A note upon active nitrogen might not be out of place here.

Strutt's method of obtaining it at atmospheric pressure (*loc. cit.*) consists essentially of sparking the gas in a fairly narrow tube, using a jar discharge to give a high current density. He finds that this, rather than voltage, is essential for the production of the gas and that whilst the discharge can produce active nitrogen, it can also destroy it; sparks up to 24 cm. in length appear to be of the maximum efficiency, and beyond that the yield of the active gas falls off rapidly. He has also shown that at low pressures the particular region of the discharge used affects the result to a considerable extent and that under any conditions of pressure a trace of impurity increases the yield.

The above mentioned conditions have been realised in the activating apparatus used by the author. The metallic copper would remove all but traces of oxygen from the nitrogen; the ozonisers used were some 22 cm. in length and the current conditions were also favourable to the formation of the active gas.

In view of the failure to obtain any evidence of nitrogen absorption under the above experimental conditions, it was decided to attack the problem from a slightly different angle.

The apparatus used is shown in Fig. 2. It was desired to produce active nitrogen under the same conditions as those obtaining in the experiments

where arcs were burned in an atmosphere of nitrogen and where the gas was known to be definitely reactive, and accordingly two of the reaction bulbs described in the first experiments were used. The electrodes

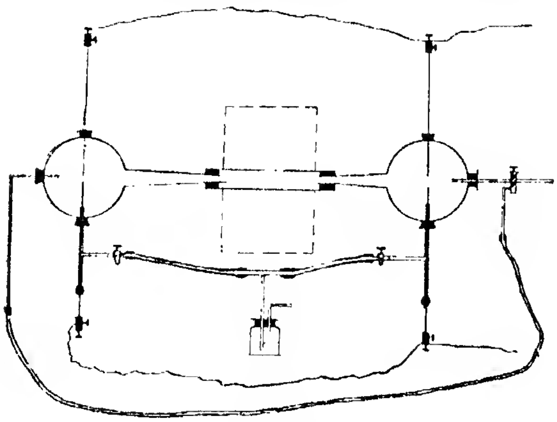

FIG. 2.

were carried vertically and the lower in each case was passed through a T-piece arranged as shown. Gas-tight joints were obtained by means of rubber sleeves and the two-way tap was employed to send the nitrogen from the purifying system through the bulb, where the arc was burning, into the furnace containing the heated iron, from thence to the second bulb and out to atmosphere *via* the taps as required. The arcs were placed in parallel as before and were burned alternately, the duration of the experiment being two hours. Traces of nitrogen only were found in the product.

From these experiments it would appear that the results obtained when the ozonisers were used are substantially correct and that exposure of heated iron to activated nitrogen does not result in any appreciable amount of absorption of the latter element.

These experiments, while interesting, were all carried out under conditions rather different from those obtaining in welding practice, inasmuch as oxygen was excluded, and since it is possible, as pointed out by Paterson and Blair, that the oxygen content of weld metal bears a relation to the amount of nitrogen present, it was decided to investigate the products obtained when iron arc is burned in air.

The apparatus used was as before (Fig. 1), with the exception that the furnace containing metallic copper was dispensed with and that the air was drawn through the apparatus by means of an aspirator; access of water vapour to the reaction bulbs was prevented by means of traps containing concentrated sulphuric acid. The current used was as before and the arcs burned well. Clouds of a brown powder formed on the bulb walls and oxides of nitrogen were distinctly perceptible in the issuing gases. A determination of the nitrogen in the product gave 0·10% and 0·12% on two series of experiments, whilst a determination of iron gave approximately 70% Fe.

This would indicate that the products consist essentially of ferric oxide and a small quantity of the nitrogenous substance. In view of the readiness with which iron becomes oxidised, the presence of this quantity of nitrogen shows that the reaction between iron and nitrogen under the influence of the electric arc must be very powerful, since the additio of 20% of such an extremely reactive element a oxygen only lowers the nitrogen content by som 50%. It is not, in the author's opinion, a valid assumption that a nitride is necessarily the only nitrogenous product in this case, since the oxides of nitrogen which are formed have to be taken in consideration. Experiments were, therefore, carri out with a view to obtain some evidence upon tha point.

It was found in the first place that upon heating quantity of the second preparation in a current hydrogen, as in the previous experiments, sma amounts of ammonia only were formed, the titre the acid in the absorbing vessels being practically t same before and after the experiment. Nitrog equivalent to 0·07% was found in the substance aft heating, from which it follows that 0·05% had bee evolved as uncombined nitrogen.

It was thought that this might be due to t accidental employment of too high a temperature the furnace, leading to decomposition of the ammo which might be formed, since Ramsay and Youn found that this was appreciable above 500°, but control experiment using the mixture of Fe_4N_2 a iron prepared by burning an arc in nitrogen gave same result as before. Hence this hypothesis not appear to be tenable.

Furthermore, upon heating in nitrogen under same conditions as were imposed for the mixtur iron nitride and iron previously obtained, the nitro content did not alter appreciably, 0·13% being fo before and 0·11% after the heating of another sam of the same preparation. Boiling with water before had little or no effect, 0·002% being evol as ammonia upon treatment in this way, and 0·00 being obtained further upon addition of alkali to distillation flask. The residue still contained 0·1 of nitrogen, and a repeat experiment using stron alkali and more prolonged boiling gave no increa yield of ammonia as compared with that stated abo

These facts would indicate that the nitrogen product obtained from the arc in air consists, in probability, of a small amount of nitride, toget with some other substance which apparently owes formation to the presence of the oxygen. It interesting to note that Sabatier and Senderens,[21] w succeeded in preparing nitro-cobalt and nitro-nic by the action of nitrogen peroxide, diluted w nitrogen, on the metals in question, were unable this method to obtain the corresponding i derivative.

It is possible that this second compound mentio above may be nitro-iron or some related substan but there is at present no experimental eviden which permits of any definite statements being mad

[20] Chem. Soc. Trans., 1884, **45**, 88.
[21] Bull. Soc. Chim., 1893, (iv.), **9**, 669.

e recent work of Partington and his collaborators on the question of nitro compounds is interesting far as this point goes.

"hen an arc was burned in the nitrogen as it came t from the cylinder, no steps being taken to ove the 1% of oxygen which it contained, the uct contained 0·10% of nitrogen and in its re- ns behaved essentially as the mixture obtained the arc in air, which would go to show that the ad nitrogenous substance may be formed in the nce of even this small quantity of oxygen.

view of the large amount of ferric oxide present as thought that the nitrogen in this case might dsorbed upon or loosely combined with the e oxide. This was tested by heating a 3-g. ple of ferric oxide to 500° in a current of gen for two hours. Traces only of nitrogen were d in both the heated sample and in the original rial used, thus disposing of the above suggestion. s a matter of interest, the mixture of iron and nitride, the product obtained by burning the n air, and some ferric oxide were all heated to redness in activated nitrogen for two hours to tain if any absorption of nitrogen took place these conditions. No nitrogen was found in esulting products except that made in air, in case the nitrogen content had not altered. addition to this, some Swedish iron was allowed idise superficially by heating to bright redness minutes in a muffle and was then heated to dness for two hours in activated nitrogen to ine the effect, if any, of the layer of Fe_3O_4, presumably would be formed. No evidence rogen absorption was found.

re is, in this connexion, considerable doubt as ether the method used for determining the en can be applied with accuracy in the case of n-nitrogen-oxygen preparation. Fixation of rogen as ammonia would presuppose a supply cent hydrogen, which was not available to any extent in this case owing to the small quantity tallic iron present. Hence the results, so far e second preparation is concerned, must be ded at present as possessing an element of t. Work is being continued upon this point. interesting possibility in the case of actual metals is that any nitro- or nitrogen-oxygen ounds present might quite conceivably give oxylamine as well as ammonia under the action e nascent hydrogen. Assuming this to be the nd bearing in mind the behaviour of free hydr- mine, we have a possible explanation of Paterson Blair's discovery that more nitrogen is obtained the distilling flask contains a zinc-copper le than when this is absent. This matter is being investigated.

general review of these experiments may now de. The main facts which would appear to be blished are as follows :—

. Upon burning an iron arc in nitrogen, appreciable ntities of iron nitride are formed. This would ear to be due to the action of the active nitrogen n the arc vapours, and affords additional evidence support of the theory that such a form of the gas is obtainable. Pre-activation of the entering gas, as well as a slight increase in pressure, does not appear to affect the amount of nitrogen absorbed.

2. Whilst the actual experimental conditions cannot be regarded as being beyond reproach, such evidence as has been obtained would go to show that exposure of heated iron to activated nitrogen does not result in any appreciable combination of the elements in question. The oxidation of the metal has no effect in this connexion.

3. Neither ferric oxide nor magnetic iron oxide absorbs nitrogen upon being heated in the gas, whether it be activated or not

4. Upon burning an iron arc in air, the products appear to contain a second nitrogenous substance, distinct from a nitride, and owing its origin to the influence of the oxygen It is suggested that this substance may be nitro-iron or some related compound formed by the action of the oxides of nitrogen upon the iron vapour or upon the iron oxide present.

5. The presence of 1% of oxygen in the atmosphere in which the arc burns is sufficient to lead to formation of the second and unidentified nitrogenous substance.

These results may now be applied to the problem under consideration—that of the nitrogen in weld metal.

In the first place, the author offers as an alternative hypothesis to Paterson and Blair's view (that the nitrogen in the weld metal is there as a result of the influence of the active nitrogen upon the weld metal itself) the suggestion that this may be due rather to an absorption of the nitride and the second nitrogenous substance from the arc vapours That this does take place is shown by the fact that the electrode tips contain nitrogen, whereas other portions of the electrode which have while heated been in contact with the active gas do not show any appreciable nitrogen content.

Secondly, Paterson and Blair's discovery that, upon heating in hydrogen, part of the nitrogen is evolved as ammonia and part as elementary nitrogen, is explained by the present author's observation that a mixture of a nitride (which yields up its nitrogen as ammonia by the action of hydrogen) and a second substance (which gives up its nitrogen in the uncombined state) is obtained by burning an iron arc in air. This fact also serves to confirm the above-mentioned workers' suggestion that the nitrogen in weld metal may be present partly as a solid solution of iron nitride and partly in some form which is related to the oxygen present.

It would, furthermore, appear probable that the nitride-nitrogen in a weld is that which is evolved as ammonia when the metal is heated in hydrogen. In the case of the figures published by Paterson and Blair, this constitutes about half of the total amount present, the remainder being presumably that which owes its presence to the oxidation effects in the arc. Hence the use of some easily oxidisable substance as a constituent of the flux on the welding rod would be expected to have a considerable effect upon the quality of the weld by reason of its tendency to inhibit formation of the iron-nitrogen-oxygen

Journal of the Society of Chemical Industry.

compound owing to preferential oxidation, and thus accordingly to lower the nitrogen content of the metal. This is borne out by the good results obtained in practice with graphite as a component of the rod coating.

The formation of nitride can probably only be minimised, and not entirely prevented, bearing in mind the circumstances of its formation, and a certain amount of nitrogen may be expected always to be present in ordinary welds made where contact with air cannot be avoided. This is obviously to be done by exposing as little iron vapour as possible to the atmosphere in the vicinity of the arc, *i.e.*, by using as short an arc as is practicable. This deduction is again supported by the experience of welding practice.

Some interesting results might be obtained by allowing a stream of some easily oxidisable gas, such as hydrogen, acetylene, etc., to impinge upon the weld from a hollow electrode holder, suitable experimental precautions being taken.

In this way, an arc might be obtained which was surrounded by an atmosphere nearly free from nitrogen or oxygen, with a correspondingly improved metal as a consequence of oxidation or nitrogenation being greatly lowered, if not prevented. This suggestion is, however, purely tentative. It may be argued that the quantity of nitrogen in weld metal would demand a high absorption of the arc vapours in order that the necessary amount of nitrogen should be present to reach the figure of 0·1% or thereabouts. For a weld made under the conditions of current density etc. employed by the present author this objection would certainly be a strong one, but it is his opinion that in industrial practice, where the current density is so much greater, the increased formation of active nitrogen will lead to much higher yields of nitride etc., which will accordingly give the observed nitrogen content. Another factor to be taken into account is the possible catalytic effects of the carbon, manganese, etc. present in the electrodes used in welding practice.

Another objection which may be raised is that Strutt (*loc. cit.*) found that 2% or more of oxygen served completely to inhibit activation of the nitrogen he used. This can be met by a consideration of the oxidation which will simultaneously be taking place. It would appear more likely that on account of the greater affinity of oxygen for iron, practically the whole of this gas may be removed locally from a small space immediately surrounding the arc, and although the whole of the atmosphere here will undoubtedly be in a state of violent motion, the oxygen content may momentarily remain low enough to permit of activation and nitride formation taking place.

The author desires, in conclusion, to express his indebtedness to Dr. J. H. Paterson and Mr. T. W. Moore for the use of their temporary laboratory, where these investigations were carried out, and to Mr. C. L. Haddon for the loan of the coil and ozonisers. He is also grateful to Profs. W. N. Haworth and H. V. A. Briscoe for the interest they have taken in the work.

THE DETERMINATION OF VANADIUM BY REDUCTION WITH HYDROGEN PEROXIDE AND TITRATION WITH POTASSIUM PERMANGANATE.

BY A. W. HOTHERSALL, B.SC. TECH.

Cain and Hostetter[1] have described a method reducing vanadium solutions by means of hydrog peroxide, and have applied it to the determinatic of vanadium in steels.[2] Lord and Demorest[3] suggest the use of this method for determine vanadium in ferro-vanadium.

The mechanism of the reduction and its appl tions in analytical chemistry do not, howe appear to have been thoroughly investigated. view of the importance of the method, the w described in this paper was carried out in order examine its efficiency and discover its limitation

The method consists essentially in adding hydro peroxide to a solution of the sample in strong phuric acid (whereby the vanadium is immedia reduced to the quadrivalent condition) and, a dilution, titration of the liquid with standard p sium permanganate. Reduction of vanadium also take place in dilute sulphuric acid solut but in this case it is necessary to allow the mix to stand in order to enable the excess of hydr peroxide to decompose before titration can be ca out.

The following procedure is recommended in of the results given later in the paper.

The method.

A suitable quantity of the sample is decom with acids, or if necessary by fusion with pota bisulphate (quantity not to exceed 10 g.), and solution filtered if required. 10 c.c. of s sulphuric acid, or 20 c.c. if much soluble m other than vanadium is present, are added, a flask is heated until fumes appear. After cool small quantity of finely powdered potassium manganate is added, and the flask again heate order to destroy organic matter) and allowed to Hydrogen peroxide solution, free from organic m and preferably containing 3% H_2O_2 or more, is a drop by drop until the excess of permanganate been decomposed and the solution has become in colour. The solution is heated until fumes to appear, and then allowed to become quite

(1) If no salts have separated, 1 c.c. of hydr peroxide solution is added drop by drop fro pipette, with constant agitation of the flask. excess of hydrogen peroxide thus introduce catalytically decomposed in a few seconds b vanadyl sulphate solution in strong sulphuric and no further heating is required. It is, how advisable to allow the solution to stand for 1 minutes, after which the test is completed by dilut to 300 c.c., heating to 70°, and titrating with stand potassium permanganate solution.

[1] J. Amer. Chem. Soc., 1912, 34, 274.

[2] U.S. Bureau of Standards, Technol. Paper No. 8 (1912). J. Amer. Soc., 1921, 43, 2552.

[3] "Metallurgical Analysis," pp. 146, 147.

(2) If basic sulphates have separated or soluble lts have crystallised, water sufficient to dissolve e separated matter, but not more than about twice e volume of strong sulphuric acid present,* is lded, and the flask warmed until solution takes ce. After cooling to room temperature, 5 c.c. of drogen peroxide solution followed by a few crystals y 0·1 g.) of potassium bromide are added. The k is then set aside, covered with a watch glass, 24 hours, after which it is heated until fumes appear (to remove bromine and hydrobromic After cooling, a little water is added and the on warmed to dissolve separated salts, diluted) c.c. (or to 700 c.c. if much iron is present), l to 70°, and titrated with standard potassium nganate, a few c.c. of syrupy phosphoric acid added to remove the iron colour if necessary the presence of large amounts of copper, iron, her elements giving coloured sulphate solutions, dvisable to make a blank determination.

is essential that the hydrogen peroxide used l be free from organic preservative, since other- ron and other elements in the solution might duced as well as vanadium. Even in their e, high and variable results are likely to be ed due to attack on the permanganate during n.

eful test for application to commercial peroxide s in evaporating 10 c.c. of the reagent with of strong sulphuric acid and a little ferric e until fumes appear. If, after cooling and , the liquid requires more standard potassium ganate solution to produce a permanent lour than does a similarly prepared solution h no peroxide has been added, the reagent be rejected.

author has found it convenient to prepare en peroxide as required by dropping sodium le into cooled dilute sulphuric acid.

duction in strong sulphuric acid solution.

liquid should be cold before the addition hydrogen peroxide, as the reaction by which um is reduced does not proceed to com- in hot solutions.

s possible by this method to determine large mall amounts of vanadium equally accurately, ate titrations invariably agreeing to within rop.

ays may be allowed to stand for long periods l tests did not exceed 2 weeks) after reduction ut affecting the titration figure provided that is excluded from the flask.

ept in very large amounts, sodium and ammon- lts do not affect the determination. Complete ion of vanadium can be effected in the presence uch as 40 g. of sodium sulphate, but owing to f loss during evaporation and of crystallisation cooling, it is inadvisable to carry out the test h more than 10 g. of these sulphates present.

* The volume of the solution, after the hydrogen peroxide has been d, should be such that the volume of added water plus that of peroxide not exceed three times the volume of strong sulphuric acid present.

The presence of up to 0·27 g. Mo, 0·38 g. As, and/ or 0·24 g. U has no effect upon the determination. Copper does not affect the reduction of vanadium, but large amounts of copper interfere somewhat with the end-point in the permanganate titration, making it necessary to carry out a blank determin- ation. In the presence of 0·25 g. Cu the blank obtained was 0·5 c.c. compared with 0·1 c.c. without copper.

Chromium interferes seriously with the deter- mination since it is reduced by hydrogen peroxide. In one series of tests, 26·4 c.c. of permanganate solution were required when no chromium was present, 26·5 c.c. with 0·035 g. (added as potas- sium dichromate), 26·85 c.c. with 0·07 g., 27·10 c.c. with 0·141 g., and 27·95 c.c. with 0·354 g. Iron has no effect on the determination provided that when the solution is evaporated to fuming with sulphuric acid there is no separation of basic sulphates, which invariably carry down vanadium with them.

Reduction in dilute sulphuric acid solution.

In order to surmount the difficulty due to the presence of iron, it is necessary to carry out the reduction in dilute solution. Auger[4] has shown that this is possible, and he states that in a 10*M* solution of sulphuric acid (about 54% by vol.) the reduction proceeds to completion in a few seconds. At greater dilutions the reduction was found to proceed more slowly. For example, with 33% H_2SO_4 in the test solution 98·8% and 99·3% of the vanadium was reduced in three days (complete reduction being obtained in 18 days) and with 25% H_2SO_4 93·5% and 93·2%.

The speed of reduction is, however, but little affected by the concentration of hydrogen peroxide.

Apparently there is a limiting concentration of sulphuric acid, lying between 20% and 33% H_2SO_4 by volume, below which the reduction will not proceed to completion.

Further experiments on the effect of concentration of sulphuric acid were carried out with the addition of potassium bromide as an accelerating agent, and it was found that complete reduction could be obtained in solutions containing 23% H_2SO_4 by volume, but not in those containing 20% H_2SO_4.

Acceleration of the reduction in dilute sulphuric acid solutions.

The effect of temperature.—If aqueous solutions containing ammonium vanadate, sulphuric acid, and hydrogen peroxide be heated, reduction of the vanadium occurs in a few minutes, but it is not so complete as when the reduction is allowed to proceed at room temperature. The degree of reduction obtained varies with the temperature of the solution (in 25% H_2SO_4, a temperature of 50° has a pro- nounced influence) but the effect is less and less marked as the concentration of sulphuric acid is increased, until with solutions containing no water (*e.g.*, strong sulphuric acid plus barium pervanadate) complete reduction of the vanadium is obtained quite independent of the temperature. This fact cannot, however, be applied to the assay as carried

[4] Compt. rend., 1921, 172, 1355.

out in concentrated sulphuric acid solution since water is necessarily introduced with the hydrogen peroxide.

The addition of a few crystals of potassium bromide greatly accelerates the decomposition of the excess of hydrogen peroxide (Bray and Livingstone[5]) and complete reduction of the vanadium can be obtained after standing for 24 hours. Before titration, however, it is necessary to boil until the bromine and hydrobromic acid formed have been removed. With this modification, the method gives accurate results in the presence of large amounts of iron (tests were made using up to 5 g Fe, added as ferric sulphate).

The application of this modified method to the determination of vanadium in steels was not investigated on account of the interference of chromium, which is almost invariably associated with vanadium in steel.

Platinised asbestos was found to act in a similar manner to potassium bromide, but it is neither so convenient to use nor so cheap as the latter. Other materials such as manganese dioxide and colloidal silica gave negative results. In the absence of iron or other easily reducible elements, metallic copper or finely divided silver, added to the assay after the hydrogen peroxide, resulted in complete reduction of the vanadium in a few seconds.

Mechanism of the reaction.

The reduction of vanadium in sulphuric acid solution by hydrogen peroxide appears to be due to the action of sulphuric acid upon pervanadic acid with the formation of vanadyl sulphate and the liberation of oxygen :—

$$4HVO_4 + 4H_2SO_4 = 2V_2O_2(SO_4)_2 + 6H_2O + 3O_2 \quad .. \quad (i)$$

Any excess of hydrogen peroxide over that required to form pervanadic acid is catalytically decomposed by the reduced vanadyl sulphate, the rate of this decomposition depending upon the concentration of sulphuric acid in the solution.

Pissarjewsky[6] states that pervanadic acid dissociates as follows :—

$$(a)\ VO_2(O_2H) \rightleftarrows VO_2^{\cdot} + O_2H'$$

$$(b)\ VO_2(O_2H) \rightleftarrows VO_2.O_2' + H^{\cdot}$$

$$(c)\ VO_2 + O_2H' \rightleftarrows VO_2.O_2' + H^{\cdot}$$

In the presence of sulphuric acid, reaction (*c*) will proceed from right to left, and when the concentration of sulphuric acid is low and these ions are able to exist without immediate decomposition according to equation (i), it appears that the

[5] J. Amer. Chem. Soc., 1923, **45**, 1251.

[6] Z. physikal. Chem., 1903, **43**, 173.

unstable ion O_2H decomposes with formation of vanadic acid and free oxygen.

$$\underbrace{VO_2 + O_2H}_{\text{Pervanadic acid}} = \underbrace{VO_2 + OH}_{\text{Vanadic acid.}} +$$

The decomposition of the O_2H ion at ordinar[y] temperatures is likely to be slow but would b[e] accelerated by heat. The equilibrium finally obtain[ed] would therefore depend upon acid concentrati[on] and temperature.

This hypothesis accounts for the slow decom[position of pure aqueous solutions of pervana[dic] acid (noticed by Pissarjewsky) and forms a re[ady] explanation of the incomplete reduction obtained [in] hot solutions. It will be recalled that the influe[nce] of temperature was found to be less the higher [the] concentration of sulphuric acid.

Summary and conclusions.

The determination of vanadium by reduction w[ith] hydrogen peroxide can be effected accurately [in] both concentrated and dilute sulphuric acid solutio[ns]. In *concentrated acid solutions* the reduction [is] immediate and complete provided an excess [of] hydrogen peroxide has not been used. In *d[ilute] acid solutions* the reaction proceeds more sl[owly] and it cannot be accelerated by heat wit[hout] oxidising a portion of the vanadium. The [com]pleteness of the reduction depends upon tempera[ture], concentration of sulphuric acid, and upon the le[ngth] of time the solution is allowed to stand. [It is] largely independent of the concentration of hyd[rogen] peroxide. In solutions containing less than [x] H_2SO_4 by volume the reduction will not proce[ed to] completion. The maximum temperature permi[ssible] lies between 25° and 50°. By the additi[on of] potassium bromide complete reduction of the [vana]dium may be obtained in 24 hours.

Of the elements tried, only chromium, whi[ch is] reduced under the conditions employed, has [an] effect upon the estimation. Certain elements, [how]ever, if present in large quantities, may [cause] mechanical interference (*e.g.*, separation of [insoluble] sulphates carrying vanadium), but this may be [over]come by carrying out the reduction in dilute sulp[huric] acid solution.

The method is applicable to a large varie[ty of] materials such as ores, ferro-vanadiums, and vana[dium] compounds of all descriptions. It can be ca[rried] out direct on these products without separatio[n of] any impurity other than insoluble matter. [The] rapidity of the method, together with its accu[racy] and reliability, render it of considerable import[ance] in analytical chemistry.

HE MECHANICAL PROPERTIES OF LUMINIUM-ZINC ALLOYS CONTAINING CADMIUM.

BY N. F. BUDGEN, M.SC., PH.D.

he object of the present research has been to rtain by the application of simple standard tific tests, the properties, other than constitu- l, of certain aluminium-zinc-cadmium alloys. work, which actually constitutes only a pre- ary survey, is intended to provide sufficient mation regarding these alloys to admit of their parison with other well-known binary and ternary s of aluminium. The only previous investigation luminium-cadmium-zinc alloys recorded is that to Bayliss and Clark,* who in 1912 examined s rich in aluminium and found that compositions ding Al 80—99, Zn 0—20, Cd 0—10%, were ble for rolling, spinning, drawing, and stamping, cientific test data in support of the claims were not published.

e constitutional conditions obtaining over the ternary system have already been investi- by the present author, and indicate that an industrial viewpoint the members which ost likely to be of value lie near the aluminium of the basal triangle representing alloy com- ons, and contain therefore a preponderance is element. In the region of the aluminium the alloys show a solid solution range which ds to a concentration of about 4% Cd and 6% uch alloys exhibit under the microscope a typical onal grain structure. The useful range of ht aluminium-zinc alloys extends almost to Zn, depending upon the purpose for which the is required, but beyond this point the alloys me too hard and brittle to be of industrial .

e range of alloys which have been examined des mixtures from 0 to 24% Zn, 0 to 10% Cd, hence 66 to 100% Al, so that a large number of compositions lie outside the area within which alloys consist entirely of homogeneous solid tion. In such cases grain boundaries, composed nly of a cadmium-zinc alloy, make their appearance micro-sections. The alloys examined cover an on the triangular basal plane, represented by small shaded parallelogram in one corner of the le ternary alloy field, Fig. 1; the lower diagram s on a larger scale the region of the alloys tigated, the position of the circles representing actual alloy compositions.

llowing careful preparation using commercially materials, the alloys were subjected to forging, rolling, and spinning tests, the cast material being tested for hardness and the cast and rolled material for tensile properties.

* Métaux et Alliages, 1914, 7, No. 5, p. 7. E.P. 19,452 of 1912. F.P. 462,361. U.S.P. 1,117,308.

Preparation of alloys.—The metals employed in this work were as follows:—

Aluminium notched bars from the British Aluminium Co.: —Si 0·20%, Fe 0·20%, Al (by diff.) 99·60%. Electrolytic zinc 99·98% pure. Cadmium, in the form of sticks of commerce, kindly presented by the British Metal Corporation: Zn 0·020%, Pb 0·013%, Cd (by diff.) 99·967%.

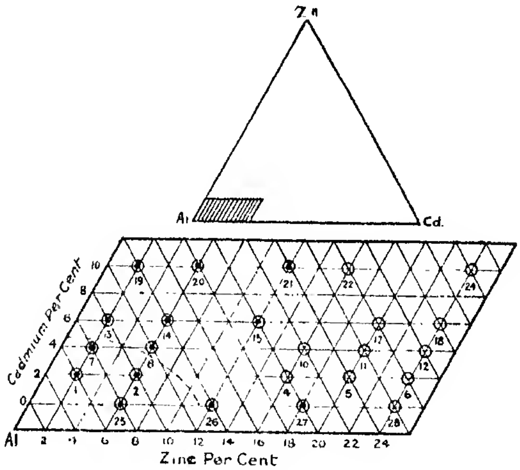

FIG. 1.

The metals in calculated and carefully weighed proportions as shown by Table I, were melted in a 12-lb. Salamander crucible, heated in a coke-fired wind furnace. The aluminium was first melted and the zinc then added whilst heating was continued until the added metal had completely dissolved; the crucible charge was then gently stirred to ensure incorporation of the zinc. The crucible was then taken from the furnace and allowed to cool to within 50° of the solidification temperature of the alloy, when the cadmium in the form of small lumps was added.

In no case on the addition of either zinc or cadmium was there any evidence of volatilisation or undue formation of oxide; a slight quantity of scum formed and was removed. Careful stirring was then applied, the charge somewhat reheated, and after again skimming was poured into a mould giving ingots measuring 4·5 × 0·5 × 10 in. and into another giving round bars 1·25 × 12 in. In every case the metal was poured at the lowest temperature at which it would fill the mould. The surfaces of most of the ingots were clean and smooth, but upon those containing 10% Cd there appeared minute beads of metal which grew uniformly to a height of about 1/16 in., evidently an exudation of some fusible constituent which was forced out on solidification of the portions of higher melting point. The beads gave

to the surfaces of the ingots a rough and speckled appearance. Fractures of the aluminium-rich alloys are more silky in appearance than those zinc- or cadmium-rich, which exhibit a granular or more coarsely crystalline structure.

Forging tests.—Forging tests were made at various temperatures on the round $1\frac{1}{4}$-inch diameter chill-cast bars. The bars covering the whole series of alloys were heated to 400° in a gas muffle near the experimental steam hammer. Each of the bars was in turn taken out and tested with the lightest possible effective blows concentrated over a length of about 3 inches of the 12-inch specimen. At 400° each of the alloys was so friable as immediately to fall to pieces before even 5% reduction in cross-section had been effected. The bars were replaced in the muffle, which was then cooled to various temperatures below 400° down to about 250°. At intervals specimens were taken out and tested under the hammer, and in each case as before fell to pieces as though made of chalk. At 250° and below, some of them forged readily whilst others split and formed considerable edge cracks. The bars were then cooled to room temperature and again tested; they forged no less well but no better than when at 250°, some of the specimens flattening out readily, whilst others immediately cracked into fragments.

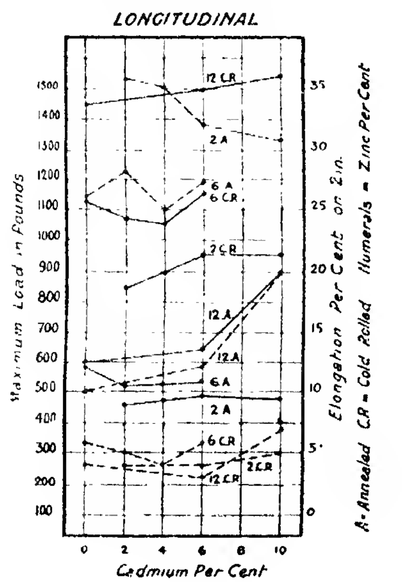

FIG. 2.

*Rolling tests.** For rolling tests the flat slabs measuring $4{\cdot}5 \times 0{\cdot}5 \times 10$ in. were employed. Portions of these were all heated to 400°, cooled to 300°, and passed through the rolls set to give a 10% reduction in thickness. At the first pass most of the specimens broke into small pieces. Lower rolling temperatures were subsequently tried, but with almost equally unsatisfactory results. The remaining portions of the slabs were cooled t[o] room temperature and rolled cold, the results i[n] general being similar to those of the forging tests o[n] the corresponding alloys. Those specimens whic[h] would roll were reduced from 0·5 in. in thickness t[o] 0·1 in. in three passes.

The rolled sheet was clean, free from spill or blister and, except in one or two cases (marked with a[n] asterisk in Table I.), practically free from edg[e] cracks. The results of the hot-forging tests we[re] thus that above 250° all of the specimens cracke[d] badly; those of the cold-forging experiments [are] given in Table I. Under hot and cold rolling [the] alloys behaved much the same as under the hamme[r] and those specimens which would not forge were a[lso] unrollable. In Table I. the specimens which w[ere] forgeable and rollable are marked "Workab[le]" and the others "Unworkable."

Spinning tests.†—Only the alloys which were cap[able] of rolling into sheet form were subjected to spin[ning] tests. The sheet, 0·1 in., was rolled down to a th[ick]ness of 0·05 in., and subjected to spinning tests u[nder] ordinary works conditions. In order first to b[ring] all of the rolled sheets to the same state, they [were] annealed at 400° for half an hour, to eliminate [the] effect of possible different amounts of cold w[ork] induced by cold rolling. The most drastic poss[ible] spinning test was applied, that is, spinning to c[up] form, the cup former having nearly parallel si[des] and being 6 in. deep. As except in the case of pu[re] aluminium, most of the alloys were hard to w[ork] cold with the forming tool, each of the discs [was] heated by gas flame to about 150°, whilst spinn[ing] was in progress, a slight continuous anneal there[by] being given. Many of the sheets withstood spinn[ing] to the whole depth of the cup and showed proper[ties] admirably suited for this purpose; a few, howe[ver] broke down at the early stages and cracked so b[adly] that further progress could not be made.

The table below indicates the behaviour of [the] the rollable alloys examined, when subjected t[o] spinning tests:—

From the data, it is seen that the strongest sheet is that containing 12% Zn, the tensile strength being 17·26 tons per square in., whilst by the addition of 10% of cadmium, the strength is further slightly increased. In this series, however, the elongation is at a minimum. It is seen that there is no marked or systematic variation in the tensile properties of aluminium-rich aluminium-zinc alloys by the addition of cadmium, though the general tendency, in the case of pieces cut longitudinally, seems to be a slight strengthening, whilst the elongation also to some

extent increases. Transverse tests appear to show almost the reverse conditions to hold.

Chill-castings.—For the purpose of tensile tests on chill-cast specimens, slabs measuring 4·5×0·5×10 in. were prepared. These were sawn along their greatest length into two pieces, and each of the latter was machined to the form of a test piece measuring 0·4 in. thick, 1·5 in. wide at the shanks, and 1·1 in. wide along the parallel portion. The alloy bars were machined by first rough-shaping on a planing machine and subsequently fine-finishing on a milling machine. The appearance of machined surfaces of specimens containing cadmium compared very favourably with those of pure aluminium or of aluminium-zinc alloys, and a highly pleasing surface was easily obtained.

After careful measurement, the specimens were tested in a Buckton 50-ton horizontal testing machine, and gave the results tabulated below and represented graphically in Fig. 4.

TABLE IV.

Chill-castings, tensile test data.

No. of alloy.	Ultimate load. Tons per sq. in.	Elongation % on 2 in.
1	7·322	36·0
7	6·948	41·0

24	10·351	0·0*

* Broke outside gauge length.

In the diagram the full lines represent tensile strength in tons per square inch and the broken lines, elongation per cent. on 2 in. The strongest alloy of the series is evidently one containing 6% Cd and 20% Zn; this shows 17·5 tons per square inch but only 3% elongation. As in the case of rolled strip, the addition of up to 10% of cadmium to the aluminium-zinc alloys examined, does not produce any very marked or systematic change in the tensile properties, but it seems that there is a slight weakening and no appreciable increase of elongation except in the case of the series containing 6% Zn.

Hardness.—Brinell hardness tests were made upon the chill-cast alloys with a 10-mm. ball and 1000 kg. load applied for 1 minute. They indicate (Table V.) a slight hardening by the addition of cadmium to each series containing a constant proportion of zinc, except in the case of the series containing 24% Zn, when softening is evidenced.

TABLE V.

Brinell hardness of chill-castings.

12	3·95	78·0
18	4·15	70·5
24	4·25	67·5

Summary.

The range of alloys examined includes mixtures taining from 0 to 24% Zn, 0 to 10% Cd, and hen to 100% Al. From certain of the alloys conta 10% Cd, small beads of a more fusible constit exude from the surface after chill-casting; th probably a cadmium-rich zinc alloy. Under hammer, all specimens cracked badly above but those containing less than a total of 18% Zn forged well below this temperature. The resu rolling tests are similar to those of forging The general effect of cadmium is to render aluminium-zinc alloys more malleable, thereby ling zinc-rich members which otherwise woul quite unworkable to be readily forged or rolle

The strongest sheet is that containing 12% the tensile strength being 17·26 tons per square whilst by the addition of 10% Cd the streng further slightly increased. In this series, how the elongation is at a minimum. There is no m or systematic variation in the tensile propert aluminium-rich aluminium-zinc alloys by the tion of cadmium. The strongest alloy of the is one containing 6% Cd and 20% Zn; this s 17·5 tons per square inch but only 3% elonga As in the case of rolled strip, there is no very ma or systematic change in the tensile properties o aluminium-zinc alloys examined, by the add to them of up to 10% Cd. Brinell hardness t indicate a slight hardening by the addition of cadm to each series containing a constant proportio zinc, except in the case of the series contai 24% Zn, when softening is evidenced.

In conclusion, the author wishes to acknowl especial indebtedness to Prof. T. Turner for gra facilities for carrying out the investigation in laboratories and for his continued interest and ad

The investigation was conducted in the Metall Department of the University, Birmingham, financial assistance from the Department of Scie and Industrial Research.

THE SPECIFIC GRAVITY AND ASH CONTENT OF COAL.

BY T. J. DRAKELEY AND J. R. I. HEPBURN.

investigation has been made to determine her a relation exists between the specific gravity sample of coal and its ash content. In a former nunication, Drakeley and Jones (J., 1923,) have examined the relation between the ic gravity and moisture content of coal.

e specific gravity and the class of coal do not r to be related in a manner which admits of any ematical treatment. All that can be stated is the older types of coal generally possess slightly specific gravities than coals of later geological s.

rder to determine the relationship, large samples (which were actually passing to washing plant) two parts of a Lancashire seam were separated fractions which floated in liquids of known c gravities.

tions of calcium chloride were first adopted as rd liquids, but were subsequently abandoned, he maximum specific gravity for a saturated n is about 1·41 and the more concentrated ns do not readily wet the coal.

ore convenient liquid, proposed by Blyth and (Trans. Inst. Min. Eng., 1918—1919, 57, 264), roform (*d* 1·5), which may be mixed with l to give solutions of any desired lower specific y. Furthermore, the chloroform-alcohol mix- possess the great advantage over salt solutions ing no residue on evaporation.

s been shown (Drakeley and Jones, *loc. cit.*) r practical purposes air-drying is satisfactory. all samples dealt with in this investigation were ted to air-drying in a laboratory in which the e humidity of the atmosphere averaged about

h bulk sample of about 1500 grams of coal was ted into fractions by flotation in solutions of sing specific gravities, the coal remaining in the l for three minutes. During the first minute olution was rapidly stirred, after which two es were allowed for settling. A suitable appara- as already been described (Drakeley, Trans. Min. Eng., 1917–1918, 55, 162), and recently, ilar form has been discussed by Sinnatt and (*ibid.*, 1923—1924, 66, 158)

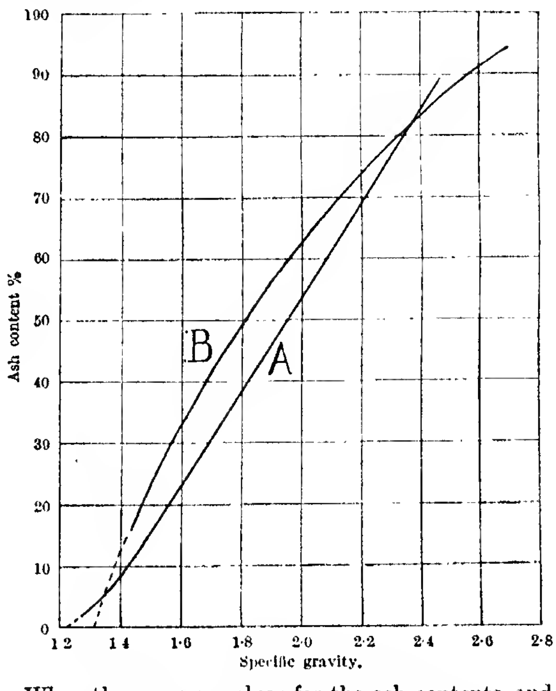
hol and chloroform were removed from each n by drying in an oven at 100°. The fractions then exposed to the air of the laboratory to each the standard conditions, and subsequently the sh content was determined.

Finally, samples of the dirt containing no visible arbonaceous matter were selected from some mined oal (from the same sources), and the respective sh contents and specific gravities were determined. The results of four tests on each bulk sample are given in Table I. :

TABLE I.

Test.	Ash content of fractions. Floating in liquid of *d* 1·30	1·35	1·40	1·45	1·49	Sinking in 1·49	Ash.	*d*.
1	2·30	4·48	7·05	10·32	13·60	52·08		
2	2·33	4·42	6·96	10·25	13·54	51·96		
3	2·36	4·47	7·02	10·30	13·60	52·01		
4	2·34	4·48	7·03	10·32	13·61	52·07	89·32	2·47
5	1·27	3·35	5·75	9·06	12·94	52·18		
6	1·27	3·38	5·77	9·10	12·96	52·21		
7	1·28	3·38	5·84	9·00	12·97	52·21		
8	1·28	3·42	5·85	9·11	12·04	52·22	90·11	2·47
Average ash content.	1·81	3·92	6·41	9·69	13·28	52·13	89·77	
Average sp gr.	1·275	1·325	1·375	1·425	1·470	1·98	2·47	

With the coals in question it was found that a liquid of specific gravity 1·25 only floated an occasional piece of coal, and therefore it may be assumed that the first fraction contained the coal particles of specific gravity ranging between 1·25 and 1·30, and averaging 1·275.



When the average values for the ash contents and specific gravities were plotted, the resulting line was found to be almost straight for the higher, but decidedly curved for the lower values (see curve A of figure). A precisely similar curve may be obtained by averaging and then plotting the results given in another connexion by Blyth and O'Shea (Trans. Inst. Min. Eng., 1918—1919, 57, 269) for coals from two Derbyshire seams

It therefore appeared that in all probability a graph such as curve A would be typical, although the graph represents a relationship which entirely disagrees with that theoretically deduced on the assumption (supported by other evidence) that a crude coal may be regarded as a mixture of clean coal and shale. A further examination therefore seemed desirable.

In a former communication, the authors (J., 1924, 134 T) have made accurate determinations of the apparent and true specific gravities of samples of a Notts hard (steam) coal, and reference may be made to the results given in that paper.

Coal samples of low ash content.

In Table I. (*loc. cit.* page 135 T) are given the true and apparent specific gravities of coal samples free from visible impurities and yielding a small quantity of ash.

In the separation effected by the flotation process, the apparent specific gravity is the controlling factor. As the separation is thus dependent on such arbitrary factors as the rate of penetration of the alcohol-chloroform mixtures, it is more likely that the true specific gravity will be related to the ash. In the event of the existence of a linear relation between true and apparent specific gravity, any relation between the true specific gravity and the ash content would also apply to the apparent specific gravity. That no relationship exists is readily demonstrated by plotting the values for the true and apparent specific gravity given in Table I., when irregularly placed points are obtained.

It has already been shown that the volatile matter and the ash content of the clean coal samples do not admit of mathematical treatment, and that the difficulty is due to the separation of the coal samples into fractions containing varying proportions of the four banded constituents

Similar reasoning accounts for the lack of regularity in the specific gravity and ash values.

Relation between the specific gravity and ash content of general coal samples.

In Table II. of this paper are given the values for the true and apparent specific gravities and the ash contents of general coal samples from the Notts. seam which yielded higher percentages of ash than those obtained in the former section :—

TABLE II.

Ash content.		16·12	27·52	32·83	39·54	46·97	51·00	52·91	69·08	75·81
Sp. gr.	Apparent	1·387	1·481	1·545	1·616	1·701	1·751	1·770	2·035	2·147
	True	1·440	1·543	1·594	1·671	1·782	1·817	1·851	2·124	2·264
	Calculated	1·443	1·540	1·605	1·688	1·775	1·831	1·853	2·125	2·268

If the true and apparent specific gravities are plotted, it will be found that an almost linear relation exists between them. This indicates that the porosity of the samples is almost constant, and that any relation between the ash content and the true specific gravity will also hold for the apparent specific gravity.

In the subsequent paragraphs, the true specific gravity is discussed in connexion with the ash content. The values for the true specific gravity and ash content are plotted in the figure and give curve B. This represents graphically the equation which may be deduced on the assumption, now shown to be true for this case, that the samples may be regarded as mixtures of coal and shale. A similar curve was obtained by Whitaker (Trans. Inst. Min. Eng., 1923, **64**, 191) for mixtures of coal and shale dusts.

The equation takes the form :—

$$1/x = y/a(1/s - 1/c) + 1/c$$

where y is the ash percentage of the sample, a that of pure shale, and c, s and x the real specific gravities of the ash-free coal, shale, and sample respectively.

In the former paper (*loc. cit.*) the value of a has been determined (95·07%) for the coal, and the value of c obtained for the curve B is 1·315. By substitution of these in the equation, x may be calculated. The results are given in Table II., and are in close agreement with the observed values for the true specific gravity.

The abnormal relation deduced in the first section of this paper may now be elucidated. In this connexion, the average specific gravity of a sample was assumed to be midway between the specific gravities of the higher and lower test solutions. This value was plotted against the ash content to give curve A. This assumption is apparently not justifiable even with narrow and certainly not with wide ranges of specific gravity, and a curve similar to B may be obtained by a slight displacement of the points. The curve will not be identical with B, which refers to a Notts coal, but an examination of a Lancashire coal gave a curve coincident with that theoretically deduced.

Iron pyrites.

The coals used in the experiments contained traces of iron pyrites. No simple relation exists for coal samples containing various proportions of this impurity, which has a specific gravity approaching 5 and yet only yields about 67% of ash on incineration in an open furnace.

Summary.

1. There exists no relation between the true and apparent specific gravities and the ash content of samples of clean coal from the same seam, owing to the fact that the sample may be composed of one or a mixture of the four banded constituents of the coal.

2. A relation exists between the true and apparent specific gravities and the ash contents of average samples, and an equation is given for calculating the ash content of the coal from the specific gravity.

3. No simple relation holds for coal samples containing varying proportions of iron pyrites.

4. It is not justifiable, in coal washing tests, to accept the specific gravity of the sample as the mean of the values for the two adjacent solutions used in float-and-sink tests.

THE DETERMINATION OF PHOSGENE.

BY H. GORDON REEVES, M.SC., A.I.C.

Although phosgene was discovered in 1811 by)avy, as yet no ready process for its quantitative letermination has been described. The present nvestigation was commenced late in 1918 when hosgene was being extensively used for war purposes, ut it was found impossible until recently to complete he work.

Kling and Schmitz (Compt. rend. 1919, **168**, 73, 891) described a method of determining one part phosgene in 10,000 parts of air by bubbling the re through aqueous aniline and determining the direct weight of diphenylurea formed or ating the weight from a nitrogen determination e Kjeldahl process. This method, although it accurate results for small amounts of phosgene, te unsuitable for rapid manipulation.

eriment showed that strong sodium hydroxide n (approx. $13N$) immediately decomposes ne, with the separation of sodium carbonate e evolution of much heat. If, however, equal s of $N/1$ sodium hydroxide and liquid phosgene ken together, decomposition of the latter is complete, some of the undecomposed phosgene on the surface of the mixture as a brownish- oil. Hence for the decomposition of the ne in the present experiments, excess of strong soda was always used. The phosgene was ned both from the excess alkali present and om the amount of chloride formed in the osition. Delépine, Douris, and Ville (Bull. him., 1920, **27**, 286) have described a very method, but merely determine the amount sgene from the total chloride formed by g with $N/40$ silver nitrate solution.

most convenient and easily manipulable of phosgene for experimental purposes was to be a solution in nitrobenzene. The latter absorbs large volumes of the gas at ordinary atures, much heat being evolved during the tion. Rise of temperature causes an immediate ion of the phosgene.

s well known that certain metals, *e.g.*, zinc, heated in an atmosphere of phosgene, decompose tter forming the chloride of the metal and ting carbon monoxide. Also numerous metallic , and mineral sulphides and other minerals venet, (Compt. rend., 1911, **152**, 87, 1250; **157**, 1153), when heated decompose phosgene ng the metallic chloride. In the case of zinc de carbon oxysulphide is formed. Experi- described below show conclusively that ne can be determined as chloride by decom- with heated zinc. Delépine, Monnot, Duval, Lafore (Bull. Soc. Chim., 1920, **27**, 292), published a method of determining hydrogen chloride as impurity in phosgene. They allow the mixed gases to act on mercuric cyanide in an evacuated bulb, and the free hydrocyanic acid is aspirated into a known volume of $2N$ sodium hydroxide solution and estimated by Déniges' method. In the work described in the present paper it is shown that the hydrogen chloride as impurity can much more readily be determined as excess chloride by decomposition of the mixed gases either with aqueous sodium hydroxide or with heated zinc.

EXPERIMENTAL.

Determination of phosgene.—A saturated solution of phosgene in nitrobenzene was contained in a round-bottom flask of 250 c.c. capacity, fitted with a two-hole rubber bung. Through one hole passed a glass tube bent at right angles and terminating in a piece of rubber tubing closed by a screw-clip, and through the other hole passed one end of a double surface condenser. The condenser was connected to three glass U-tubes, each containing 10 c.c. of $13N$ sodium hydroxide solution. In order to prevent bumping and to ensure steady evolution of gas, small pieces of porous earthenware were added to the nitrobenzene solution. The round-bottom flask was heated on the water bath, and heating was continued until phosgene ceased to be evolved from the solution. Rapid evolution commenced at 75°, and one hour's heating sufficed for complete removal of the dissolved phosgene. Dry air was then bubbled through the whole apparatus *via* the tube carrying the screw-clip, in order to drive the last traces of phosgene forward into the absorption tubes. The contents of each U-tube were made up to 500 c.c. and titrated against $N/1$ hydrochloric acid solution. The amount of alkali used in the decomposition of the phosgene was thus arrived at by difference. In a typical analysis 4·734 g. of phosgene were found when 5 g. were used. The discrepancy was traced to the presence of free chlorine as impurity in the phosgene from the cylinders supplied for use.

This free chlorine was determined in two ways:—(1) The contaminated phosgene was passed through dilute potassium iodide solution and the iodine liberated determined by titration with standard sodium thiosulphate solution (Delépine, Bull. Soc. Chim., 1920, **27**, 283). The amount of free chlorine indicated by the method was 3·6–4%. (2) Known weights of liquid phosgene and mercury were shaken together in a bulb immersed in a freezing mixture. The phosgene was allowed to gasify, and from the increase of weight of mercury the amount of free chlorine was calculated.

The chlorine was removed either by passing the phosgene from the cylinder, through tubes containing respectively, powdered antimony, zinc dust, and calcium chloride, or more conveniently and much more rapidly by adding pieces of iron wire to the nitrobenzene before saturation. The iron removes the chlorine and at the same time a small amount of *m*-nitrochlorobenzene is produced. The phosgene thus freed of impurity was re-absorbed in nitrobenzene ready for use.

In the following series of experiments pure phosgene was employed, and its weight was estimated both as chloride and as carbonate (double indicator or B.D.H. universal indicator). Also, as a further precaution, five absorption tubes were used instead of three as previously.

Determination of $COCl_2$ as carbonate

No.	Wt. of $COCl_2$ taken. g.	Total wt of CO_2 found. g	Equivalent wt. of $COCl_2$ g.
1	5·20	5·15	4·814
2	5·60	5·87	5·480
3	4·80	5·097	4·760

Determination of $COCl_2$ as chloride

No.	Wt. of $COCl_2$ taken.	Total wt. of Cl_2 found.	Equivalent wt. of $COCl_2$.
1	5·20	3·53	4·92
2	5·60	4·00	5·58
3	4·80	3·44	4·79

Determination of free hydrogen chloride in phosgene.—By the above method it was found possible to determine hydrogen chloride as impurity in the phosgene. A known weight of pure dry hydrogen chloride gas at room temperature was introduced from a burette into a known weight of pure phosgene, and the mixed gases were passed forward into the decomposition tubes. The amount of free hydrogen chloride was obtained by the difference between the total chloride formed and that due to the decomposition of the phosgene.

Decomposition and determination of phosgene by means of heated zinc.—Phosgene (purified by passing through tubes containing respectively powdered antimony, zinc dust, and calcium chloride) was driven off from nitrobenzene solution and passed over heated asbestos impregnated with pure zinc dust (freed from chloride by repeated extraction with dilute acetic acid, washed with alcohol, and finally dried) contained in a combustion tube, 2 ft. long, supported in a furnace. The phosgene was passed over the heated zinc and heating was continued for three hours. As a precaution three U-tubes containing sodium hydroxide were fitted on to the combustion tube for the purpose of trapping any phosgene which escaped decomposition by the heated zinc. When cool the contents of the combustion tube were washed with pure dilute nitric acid into a large beaker. The asbestos was removed by filtration, carefully washed free from chloride, and the combined filtrate and washings were made up to a litre. 50 c.c. of the solution were mixed with 25 c.c. $N/10$ silver nitrate and titrated against $N/10$ ammonium thiocyanate. In a typical analysis in which the weight of phosgene taken was 2·38 g. the amount found was 2·37 g. Thus no ph... had escaped decomposition in the heated tub...

Determination of free hydrogen chloride.—... above method is most convenient for the determ... tion of free hydrogen chloride admixed with phos... The apparatus finally used is indicated in ...

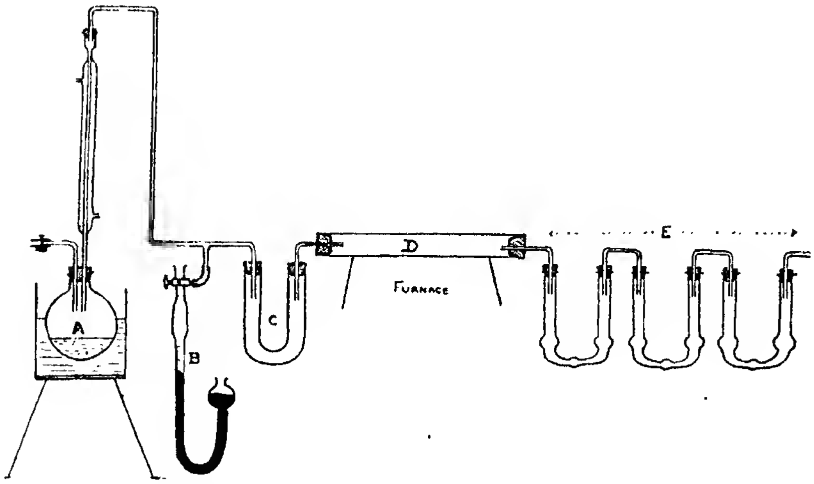

figure. Pure phosgene was driven off from the benzene solution contained in the flask, A, mixed with pure dry hydrogen chloride gas fro... burette, B. The mixed gases then passed through the cold U-tube, C, containing glass coated with pure zinc dust, next through the ...bustion tube, D, and finally into the absor... tubes, E, containing sodium hydroxide.

The amounts of chloride in C and D were separ... determined with silver nitrate and thiocya... No phosgene escaped decomposition in D.

In one analysis the weight of phosgene taken 4·09 g.; found 4·08 g. The amount of free h... gen chloride calculated was 9·64%, and the am... determined 9·58%.

In conclusion, I wish to thank Prof. P. F. Frank... for suggesting the work and for his kind interest... valuable advice throughout the investigation, ... also Mr. S. R. Carter for his help and criticism.

THE DETERMINATION OF PHOSGENE.

BY H. GORDON REEVES, M.SC., A.I.C.

Although phosgene was discovered in 1811 by)avy, as yet no ready process for its quantitative letermination has been described. The present nvestigation was commenced late in 1918 when hosgene was being extensively used for war purposes, ut it was found impossible until recently to complete he work.

Kling and Schmitz (Compt. rend. 1919, **168**, 73, 891) described a method of determining one part phosgene in 10,000 parts of air by bubbling the re through aqueous aniline and determining the direct weight of diphenylurea formed or ating the weight from a nitrogen determination Kjeldahl process. This method, although it accurate results for small amounts of phosgene, e unsuitable for rapid manipulation.

riment showed that strong sodium hydroxide n (approx. 13N) immediately decomposes ne, with the separation of sodium carbonate e evolution of much heat. If, however, equal s of N/1 sodium hydroxide and liquid phosgene ken together, decomposition of the latter is complete, some of the undecomposed phosgene on the surface of the mixture as a brownish- oil. Hence for the decomposition of the e in the present experiments, excess of strong soda was always used. The phosgene was ined both from the excess alkali present and om the amount of chloride formed in the osition. Delépine, Douris, and Ville (Bull. him., 1920, **27**, 286) have described a very method, but merely determine the amount sgene from the total chloride formed by g with N/40 silver nitrate solution.

most convenient and easily manipulable of phosgene for experimental purposes was to be a solution in nitrobenzene. The latter absorbs large volumes of the gas at ordinary atures, much heat being evolved during the tion. Rise of temperature causes an immediate on of the phosgene.

s well known that certain metals, *e.g.*, zinc, heated in an atmosphere of phosgene, decompose tter forming the chloride of the metal and ting carbon monoxide. Also numerous metallic , and mineral sulphides and other minerals venet, Compt. rend., 1911, **152**, 87, 1250; **157**, 1153), when heated decompose phosgene g the metallic chloride. In the case of zinc de carbon oxysulphide is formed. Experi- described below show conclusively that ne can be determined as chloride by decom- g with heated zinc. Delépine, Monnot, Duval, Lafore (Bull. Soc. Chim., 1920, **27**, 292), published a method of determining hydrogen chloride as impurity in phosgene. They allow the mixed gases to act on mercuric cyanide in an evacuated bulb, and the free hydrocyanic acid is aspirated into a known volume of 2N sodium hydroxide solution and estimated by Déniges' method. In the work described in the present paper it is shown that the hydrogen chloride as impurity can much more readily be determined as excess chloride by decomposition of the mixed gases either with aqueous sodium hydroxide or with heated zinc.

EXPERIMENTAL.

Determination of phosgene.—A saturated solution of phosgene in nitrobenzene was contained in a round-bottom flask of 250 c.c. capacity, fitted with a two-hole rubber bung. Through one hole passed a glass tube bent at right angles and terminating in a piece of rubber tubing closed by a screw-clip, and through the other hole passed one end of a double surface condenser. The condenser was connected to three glass U-tubes, each containing 10 c.c. of 13N sodium hydroxide solution. In order to prevent bumping and to ensure steady evolution of gas, small pieces of porous earthenware were added to the nitrobenzene solution. The round-bottom flask was heated on the water bath, and heating was continued until phosgene ceased to be evolved from the solution. Rapid evolution commenced at 75°, and one hour's heating sufficed for complete removal of the dissolved phosgene. Dry air was then bubbled through the whole apparatus *via* the tube carrying the screw-clip, in order to drive the last traces of phosgene forward into the absorption tubes. The contents of each U-tube were made up to 500 c.c. and titrated against N/1 hydrochloric acid solution. The amount of alkali used in the decomposition of the phosgene was thus arrived at by difference. In a typical analysis 4·734 g. of phosgene were found when 5 g. were used. The discrepancy was traced to the presence of free chlorine as impurity in the phosgene from the cylinders supplied for use.

This free chlorine was determined in two ways:—(1) The contaminated phosgene was passed through dilute potassium iodide solution and the iodine liberated determined by titration with standard sodium thiosulphate solution (Delépine, Bull. Soc. Chim., 1920, **27**, 283). The amount of free chlorine indicated by the method was 3·6–4%. (2) Known weights of liquid phosgene and mercury were shaken together in a bulb immersed in a freezing mixture. The phosgene was allowed to gasify, and from the increase of weight of mercury the amount of free chlorine was calculated.

The chlorine was removed either by passing the phosgene from the cylinder, through tubes containing respectively, powdered antimony, zinc dust, and calcium chloride, or more conveniently and much more rapidly by adding pieces of iron wire to the nitrobenzene before saturation. The iron removes the chlorine and at the same time a small amount of *m*-nitrochlorobenzene is produced. The phosgene thus freed of impurity was re-absorbed in nitrobenzene ready for use.

In the following series of experiments pure phosgene was employed, and its weight was estimated both as chloride and as carbonate (double indicator or B.D.H. universal indicator). Also, as a further precaution, five absorption tubes were used instead of three as previously.

A pressure equaliser.—In many chemical operations, such for example as the preparation of ethylene, where a gas is either going to be washed through columns of liquid or to be passed into bromine as in the preparation of ethylene bromide, or in similar cases where a back pressure is developed, it is generally found that the preparation of the gas is hindered by the fact that this back pressure prevents the flow of liquid into the generating flask, and that gas often bubbles up in the opposite direction from that desired. The sketch, Fig. 3, shows a very simple and a very efficient method by means of which this drawback can be obviated. The preparation of ethylene may be taken as an example. Into the apparatus there is introduced at A a glass T-piece, and this is connected by means of rubber tubing with a bent glass tube, B, passing through a rubber cork fitted into the neck of the dropping funnel. The pressures in C and D are thus immediately equalised and liquid will flow from D into C no matter what the back pressure may be. This has, of course, the disadvantage that if the back pressure is too great the flask, C, might burst or the stopper blow out of it; but this can very easily be provided for in the already well known way by a T-piece, E, dipping into mercury or some other suitable liquid. This very simple device will certainly be found useful in many cases.

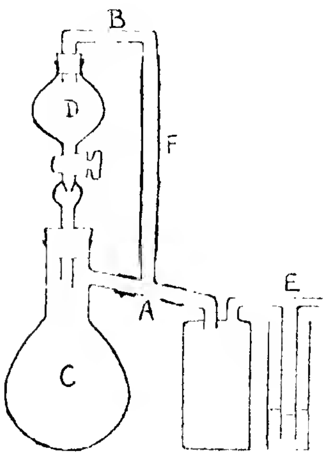

FIG. 3.

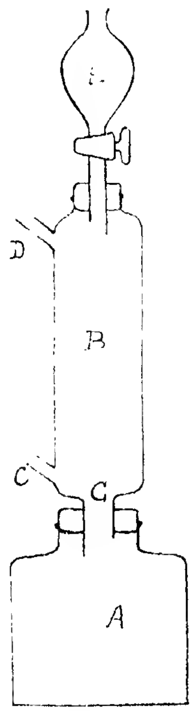

FIG. 4.

A fume absorber for the laboratory.—The piece of apparatus shown in Fig. 4 will be found useful for connecting up the apparatus in which a reaction is being carried out, producing acid fumes or some other easily absorbable substance, such as ammonia. In the preparation, for example, of acetyl chl considerable quantities of hydrogen chlo given off, an inconvenience well known chemists. The same inconvenience is alw enced when an apparatus for generatin

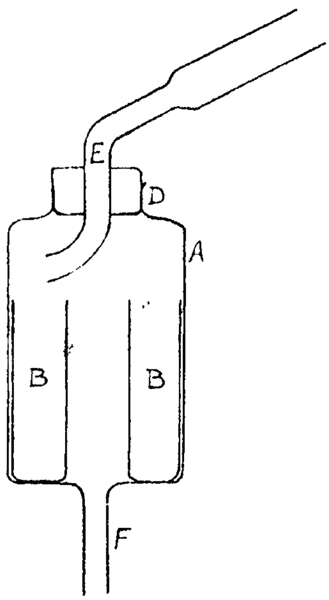

FIG. 5.

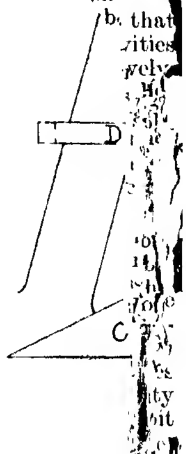

FIG. 6

chloride from concentrated hydrochloric ac sulphuric acid is used intermittently, and be left standing in a fume cupboard. The ap consists of a wide-mouthed squat bottle, which is fitted a wide glass tube, B, the low being constricted and passing through a cork fits into A. There are short side tubes at C B is filled with broken pieces of pumice which are kept from falling into A by some wool at G. The upper part of B is also cons and fitted with a cork through which pa dropping funnel, E, from which water may be to flow down over the pumice stone at such as may be convenient. The exit tube of an app in which, for example, hydrogen chloride is pro as a by-product, is attached by rubber tubing The hydrochloric acid is completely absorbed water trickling over the surface of the pumice There is no back pressure, and owing to the upward slope of C there should be no danger of the water sucking back through C into the re apparatus.

Vacuum distillation receiver.—The sketch in shows an apparatus which will be found usef the distillation of small quantities of liquids reduced pressure. It consists of a tube, A, internal diameter and having a neck, D, $\frac{3}{8}$ in. internal diameter, the other end being with a narrower tube, F, sealed on as shown. Si specimen tubes, B, B, 2 in. by $\frac{7}{16}$ in. (four or fi according to size), are then dropped into A, and ca be fixed in position round the walls of the larg

y pushing a piece of cotton wadding into the between them. The neck of the tube, D, d by means of a rubber cork, through which tube of a distilling flask, or an adaptor, E, as shown in the sketch. Air is pumped gh F, and when the distillation commences B, can be brought successively into position g the whole receiver around E. This may also be made in larger sizes suitable dinary work. An outer vessel 7 cm. in diameter with a neck 3 cm. in diameter, three tubes 10 cm. long by $2\frac{1}{2}$ cm. diameter 6 smaller tubes. Length of cylinder A, 7 cm.

m-wire press.—The sodium-wire press is fitted with a die provided with a small hole which the sodium is squeezed. It hastens reatly the preparation of sodium-wire for emical reactions if a number of holes, five or bored in the die.

t-tube stand.—Fig. 6 shows the end section t-tube stand of useful form. It consists of a wood, AB, to which is affixed another strip, l with holes, through which the wider end t tube may pass, and another strip, C, cut ngle. The test tube, after washing, is placed position shown in the figure, the upper part nto grooves at A. Moisture drains down the the point at which the lip touches C, and away completely. It is thus easy to keep tube both clean and dry. This test tube supplied by Messrs. Gallenkamp, London.

TALYSIS AND THE INTERNAL COMBUSTION ENGINE.*

BY EDWARD SOKAL.

l years ago an experimental and subsequently strial investigation was undertaken by the along the lines of applying the principle of s and the use of catalytic agents to the combustion engine. The starting point thought that nearly all the ailments and of the internal combustion engine, apart he purely mechanical constructive features, ue to the same basic phenomenon, namely, lete combustion of motor fuel within the l combustion engine. It occurred to the that it might be possible to promote com- by bringing the mixture of fuel and air combustion chamber into contact with a ent, solid catalytic agent.

the time interval during which useful com- n can take place in a motor is limited by the tion of the power stroke, it seems plausible t an acceleration of the combustion under these circumstances would effect a more complete combustion. Moreover, elementary thermodynamic considerations show that in the Otto or constant-volume cycle, on which the majority of the internal combustion engines and practically all motor engines operate, the heat transfer to the expanding medium is supposed to take place at constant volume or as nearly constant volume as possible, any deviation from this implying a loss in thermal efficiency: in other words, two engines showing the same exhaust gas analysis might have a greatly different thermal efficiency according to whether the process of combustion has taken place before the piston has moved appreciably or has extended and continued during a considerable part of the power stroke. From this basic theoretical starting point the author has been led to experimental work, which afterwards has been continued on an industrial scale, and is now applied successfully to commercial practice in the form of a catalytic coating called "Katalite," which is applied to the cylinder heads, and sometimes also to the pistons and spark plugs of automotive engines.

The combustion of motor fuel within the internal-combustion engine is a chemical reaction which cannot be properly allocated as either homogeneous or heterogeneous. It is started from one or several points according to whether simple or multiple ignition is employed, but the great turbulence prevailing within the combustion chamber gives it to a certain extent the character of a homogeneous reaction, and to this extent only the Guldberg-Waage law of mass action influences the speed of this combustion. This same phenomenon of turbulence explains why the very limited wall surface which can be coated with the catalytic agent can produce marked results. In this way the effect of the catalytic agent becomes analogous to the often, although unsuccessfully, attempted method of stratifying the fuel into leaner and richer layers, the latter ones being adjacent to the point of ignition. There is, however, this important difference, that stratification, which gives truly remarkable results under special laboratory and limited speed conditions, does not work satisfactorily in practice because it is destroyed by turbulence at higher speeds, whilst the effect of a catalytic layer on the surface of the combustion chamber is markedly increased by turbulence, each particle of fuel-air mixture that comes in contact with the coating acting like a stratified rich mixture.

Several years ago, the author, with the collaboration of Prof. E. H. Leslie of the University of Michigan, investigated various catalytic agents as to their fitness for the intended application to internal combustion engines. It was clear from the beginning that certain fundamental requirements had to be fulfilled in order to make this application possible. Besides the obvious commercial requirements of availability and price, the material selected had to exert a very pronounced catalytic effect on combustion and at the same time should not catalyse other undesirable reactions, as for instance, cracking and decomposition of the fuel, furthermore, it had to be refractory, non-abrasive, resistant to poisoning, susceptible of being spread with the use of a suitable

* Read at a meeting of the American Section on March 21, 1924.

binder as a resistant, adhesive, and permanent layer on the walls of the combustion chamber, and, last but not least, it should have a high coefficient of radiation, so that the heating effects of the combustion should not by accumulative increase bring about pre-ignition. The above requirements obviously limited the selection of suitable catalysts to certain classes of substances and to a still smaller number of preferential selections within these classes. Carefully made experiments, in which fuel-air mixtures of various compositions and proportions were permitted to flow at a predetermined speed and under exactly controlled conditions of temperature etc., once through ordinary tubes and then through tubes in which they encountered pieces of pumice stone impregnated with catalytic agents, demonstrated clearly that it was possible to find catalytic agents which would comply with the above-mentioned requirements and still accelerate the rate of combustion of various motor fuels over a thousand times. From this the conclusion was drawn that it ought to be possible to carry out the idea in practice and to obtain the desired improvements, provided, of course, that the fundamental conception was sound.

Amongst the catalysts which comply most closely with the above requirements, the metallic oxides, *e.g.*, vanadium oxide, cobalt oxide, rare earth oxides, and particularly cerium oxide on account of its high coefficient of radiation, have proved highly satisfactory.

Experience has fully confirmed this conclusion. Observations on several hundred cars, extending now over a period of more than two years, and in certain cars over a service range of more than 20,000 miles, have shown that the effect of a catalytic coating applied on a combustion chamber of an automotive engine is marked and permanent; no experiments have been made on other than automotive engines. In some engines, which have a large margin of cooling capacity, it has been found possible to increase the maximum power appreciably, but in all cases it is possible to duplicate the present optimum performance with a very much leaner mixture. An average of a great many tes shows the attainable fuel economy to be over 20% The carbon deposit is greatly diminished, rath soft and sooty, and does not interfere with th catalytic action. Performance tests have prov a decided improvement in flexibility, hill climbi etc. Experiments made under special conditi by the Locomobile Company have also clea confirmed the prediction that the catalytic coat has a decided tendency to counteract deto tion.

The curious phenomenon of detonation or f knock is not to be confounded with pre-igniti and is characterised mainly by abnormally hi pressures occurring during the power stroke lasting an infinitesimally small time only, s they can do no useful work and are only dest impacts. Midgley has found various chemica stances (*e.g.*, lead tetra-ethyl) which added fuel stop detonation, and has tried to explain ation as being due to too rapid combustic the author's opinion this explanation does n good from the standpoint of laws of physical istry. On the other hand, all the phenom detonation seem easily explained if attribu the thermal decomposition of the large fuel mo into a number of smaller molecules with sponding increase of local pressure. It is inter to note that the tendency of fuels to detonate ishes with their thermal stability, as eviden alcohol and benzol. "Katalite" counteracts ation because it accelerates combustion, but ation may also be counteracted by negative ca which might retard the decomposition of fu

So far, the catalytic coating called "Kat has been used in engines as they are now, w any change in the engine. It is considered as p and even probable that with certain chang for instance, increase of the surface of the com chamber, much greater effects could be pr which might have a bearing on the utilisat low-grade fuels, running of engines at co compression pressure, and various other qu of design and operation.

...asured volume of the mixture is boiled, and ...ours are led over calcium carbide. The ...e formed is separated from alcohol and ...y passing through concentrated sulphuric in potassium hydroxide solution of this concentration.

The apparatus used is shown in Fig. 1. It was found that carbon dioxide, either from cylinders or generated from hydrochloric acid and marble, contains, in every 250 c.c., 0·7—0·9 c.c. of gas which is not absorbed in potassium hydroxide solution, and therefore the volume of carbon dioxide used for clearing the apparatus of acetylene must be known, in order that a deduction may be made to allow for this insoluble portion. Hence the carbon dioxide is supplied from a graduated gasometer. The prolonged end of the burette, R, extends to the bottom of the boiling tube, E, where it dips under mercury. By this means the escape of ether vapour through the channels cut out by it in the lubricant of the burette tap is prevented. The metal plate under the tube, G, is heated when it is desired to re-volatilise any vapours which have condensed in G whilst passing from the boiling tube. The bubblers, H and I, are cooled in water to prevent excessive rise in temperature of the sulphuric acid due to absorption of the alcohol and

Acetylene is practically insoluble ether. When the acid in the bubbler, H, is spent it may be replaced without the admission of air to the apparatus by closing the screw clip, X, and opening the tap, T, when the pressure of the carbon dioxide from the gasometer will be sufficient to drive out the acid. The tap, T, is then closed. To introduce fresh acid the screw clip, Y, is closed and the clip, X, opened; the reservoir, S, is filled with acid and the required quantity forced into H by pressure from the bottle, P. This latter also

* Read at a meeting of the Sydney Section on May 14, 1924.

supplies the necessary pressure to force the mixture from the burette into the boiling tube against the pressure of the carbon dioxide within. Except in the cases of D and H, which are entirely of glass, each vessel is provided with a rubber stopper, and all connexions are made with stout pressure tubing securely wired. It was found that a preliminary heating at 100° prevented the occurrence of error due to liberation of any moisture from the rubber stopper of the boiling tube.

Experimental method.

The boiler is heated at 100° by means of the steam jacket, whilst a current of dry carbon dioxide is passed to clear the apparatus of air. Usually from 500 to 750 c.c. of carbon dioxide must be employed for this purpose, the current being continued until, of 250 c.c. passed through the apparatus, only 0·8—1·0 c.c. is not absorbed by the potassium hydroxide solution. The heating is discontinued at the end of the first fifteen minutes. When the air has been displaced the boiler is allowed to cool and the screw clip, Z, closed. The required volume of mixture is then forced into the boiler; the amount to be used depends on the water content; thus, for mixtures containing less than 0·5% of water, 10 c.c. were used; for mixtures containing between 0·5 and 2·0%, 5 c.c.; and for mixtures containing more than 2·0%, 2·5 c.c. The mixture is caused to boil gently by passing a very slow current of steam through the jacket, care being taken to prevent too rapid ebullition. When all the mixture has been evaporated the condensed vapours in G are re-volatilised by warming the plate, O, and the screw clip, Z, is opened slightly to permit the passage of a slow current of carbon dioxide. This current is continued until all the acetylene has been swept over; the tube connecting E and G is warmed meanwhile to re-volatilise vapours condensed therein, the boiler being also heated at 100° by passing a rapid current of steam through the jacket. Usually between 500 and 750 c.c. of carbon dioxide are required to clear the apparatus. From the volume of the gas in the nitrometer is deducted an amount determined by the volume of carbon dioxide used (as explained above); the remainder is taken as the volume of acetylene produced.

In the first bubbler, H, 33—40 c.c. of sulphuric acid will absorb 20 c.c. of a mixture of ether and alcohol before requiring renewal, whilst the acid in the second bubbler, I, rarely needs changing, because absorption is practically complete in H. The frequency with which the calcium carbide should be renewed depends on the water content of the mixtures under examination, but after ten determinations, when a total of 0·5 g. of water had passed, it was found to be still effective. The calcium carbide used was of the ordinary commercial variety, and results from various samples did not vary appreciably.

Anæsthetic ether, *d* 0·720, was subjected to analysis in the apparatus, and 10 c.c. gave 10 c.c. of acetylene. After drying over metallic sodium for one month and distilling through a twenty-[illegible] fractionating column and condenser, the frac[...]tion distilling between 34·3° and 34·4° was examined[...], and 10 c.c. gave 1·7 c.c. of acetylene. A sample of [...] 10 c.c. of ether which had been dried over meta[...]llic sodium for 6 months gave 1·6 c.c. of acetyl[...]ene. It is therefore assumed that the ether is [...] not dried absolutely by sodium.

To te[...]st the apparatus various mixtures of known compo[...]sition were made and examined. To the ether [...] dried over sodium were added known amounts of aqu[...]eous alcohol of known water content, and readings [...] were taken. From the volume of acetylene obtained [...] a deduction was made for that part of the readin[g ...] due to the water in the original ether, and thus the [...] actual increase of volume of acetylene for known [...] in water content was arrive[d] at. Variation of the [...] concentration of the aqueous alcohol used as diluent [...] did not appreciably affe[ct] the results.

The following is a summary of the results ob[tained] (see also Fig. 2):—

Increase in water content in grams per 10 c.c. of mixture.	Mean.		Increase (over 1·7 c.c. ...) at 20° of acetylene obtained from 10 c.c. of mixture.		Mean.

Increase in volume of acetylene in c.c. obtained from 10 c.c. of [...]

FIG. 2.

The driest ether obtainable gave a readin[g of] 1·7 c.c. (*cf. supra*); since this volume was prob[ably] due to unremoved water it was necessary to a[rrive] at the actual amount of water present. Thi[s was] done by plotting a curve of increase of volum[e over] 1·7 c.c. against increase in water content [...]

and producing back a distance OA corresponding o a volume of 1·7 c.c., the new point O[1] being the new zero. From the result of this extrapolation t seems that there was probably 0·0120 g. of water per 10·0 c.c. in the dry ether (0·14% by weight). The figures representing increase in water content are therefore increased by 0·0120 g. to represent he true water content; similarly, the figures representing the increase in volume are increased by 1·7 c.c. to give the true volume of acetylene.

The new table is then as follows:—

Water content in g. per 10 c.c. of mixture.		Vol. at 20° of acetylene obtained from 10 c.c. of mixture. c.c.	Water content in g. per 10 c.c. of mixture.		Vol. at 20° of acetylene obtained from 10 c.c. of mixture. c.c.
0·0120	..	1·7	0·0801	..	44·7
52	..	2·8	0·0955	..	55·0
79	..	2·95	0·1070	..	60·3

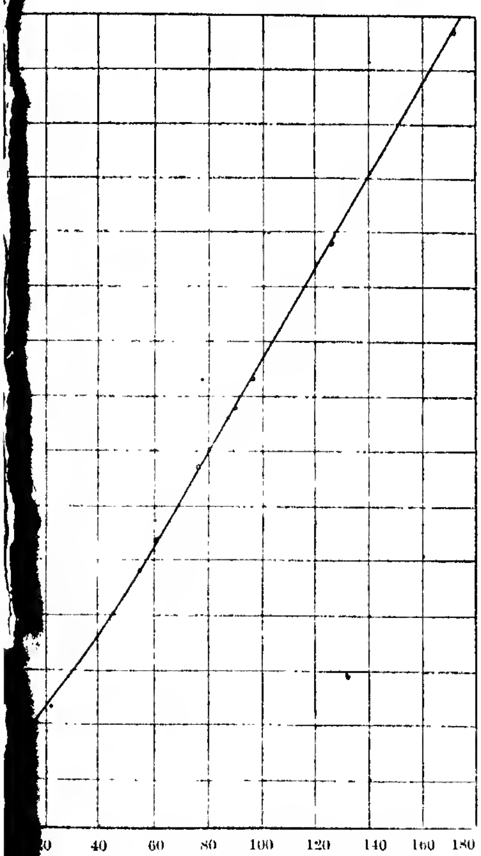

FIG. 3.

curve, Fig. 3, plotted from these results straight line except for the portion near the gin, where it becomes convex to the vertical s. This indicates an expected decrease in sensieness as the water content diminishes, due to the difficulty of bringing all the water vapour into contact with the calcium carbide when it constitutes only a small proportion of the mixed vapours. When the mixture contains more than 1·25% of water, 1·0 c.c. of acetylene at 20° is obtained from 0·00172 g. of water, although theoretically 0·00162 g. of water gives 1 c.c. of acetylene at N.T.P. P. V. Dupré, when using calcium carbide to determine water in ammonium oxalate, cordite, naphthalene, etc. (Analyst, 1906, 31, 213), found that 1 c.c. of acetylene was obtained for every 0·001725 g. of water present, but in that case the acetylene was measured direct and underwent no treatment such as passing through sulphuric acid.

Preliminary enquiries indicate that the method is applicable to the determination of water in aqueous alcohol, and it is intended to make this the subject of further investigations.

The author wishes to express his thanks to Prof. Schofield for suggesting this line of research, to Acting-Professor Harker for advice during the progress of the work, and to Mr. P. G. Carter for drawing the diagram and graphs.

The University,

THE ACTION OF OZONE ON HYDROCARBONS, WITH SPECIAL REFERENCE TO THE PRODUCTION OF FORMALDEHYDE.

BY E. W. BLAIR, D.I.C., B.SC. (LOND.), A.I.C., T. S. WHEELER, PH.D., B.SC. (LOND.), F.R.C.SC.I., F.I.C., and W. LEDBURY, M.SC., A.I.C.

PART III.—THE ACTION OF OZONE ON n-HEXANE.

In papers published by two of the authors (J., 1922, 331 T; 1923, 343 T) investigations have been described dealing with the action of ozone on methane and ethylene, particular attention being paid to the production of formaldehyde. The action of ozone on higher unsaturated hydrocarbons has been investigated and does not, as is well known, differ materially from its action on ethylene; on the other hand, the action of ozone on the higher saturated hydrocarbons does not seem to have been studied, at least quantitatively. In the present investigation the action of ozone on n-hexane, at the boiling point, was investigated.

Apparatus and methods.

Air or oxygen, after passing through a rate-gauge, was freed from dust and carbon dioxide, thoroughly dried by concentrated sulphuric acid and phosphorus pentoxide, and then led through an ozoniser into pure boiling n-hexane, which had previously been three times fractionated to within 0·2° and was contained in a flask heated on a water-bath and fitted with two vertical condensers in series. The gas then passed through three wash-bottles in series, through potassium iodide solution in order to destroy any unused ozone, through a bubbler containing baryta water to show the presence of carbon dioxide,

and then through palladous chloride solution to test for carbon monoxide. All joints in the apparatus were of ground glass.

The quantity of gas passed was determined by noting the average rate of passage and the duration of the experiment from the time the hexane commenced to boil until the experiment was discontinued. The air used was taken directly through a reducing valve from a compressed air supply; oxygen, when employed, was drawn from a cylinder. The percentage of ozone was determined at intervals of one hour, using a three-way tap, which enabled the ozone in a measured quantity of the gas coming from the ozoniser to be determined (see Analyst, 1923, 48, 110.) The determination had to be made at hourly intervals since, if the concentration of the iodine, liberated from the potassium iodide, was allowed to increase, a reaction to produce iodoform took place between it and a small quantity of acetaldehyde, which escaped absorption by the wash-waters.

Experimental results.—During an experiment no fumes were observed in the apparatus as a result of the action of the ozone on *n*-hexane. In the baryta bubbler barium carbonate was gradually deposited, whilst the very slow formation of a precipitate from the palladous chloride solution indicated the presence of traces of carbon monoxide. In all the bubblers a small quantity of hexane was condensed, and the gas issuing from the apparatus had a slight odour of it.

The residue in the reaction flask at the conclusion of the experiment formed two layers, both of which possessed a strong odour of fatty acids. The lower layer, which was much the smaller in bulk, contained no hexane; the upper consisted chiefly of that hydrocarbon. The following detailed account of an experiment will make clear the methods adopted to examine the products and the results obtained.

Description of an experiment

Initial content of refluxing flask—200 c.c. of redistilled *n*-hexane.

O_3 applied, 661·5 c.c.

O_3 not reacting (from liberation of I_2 in KI bubbler), 168·0 c.c. Total volume of residue in flask at conclusion of experiment, 152 c.c.

The residue formed two layers, the lower having a volume of about 10 c.c. This had a total acidity equivalent to 41 c.c. of $N/10$ alkali =(if only monobasic acid is present) 91·8 c.c. of acid as vapour at N.T.P. There were also present formaldehyde (shown by potassium cyanide test), acetaldehyde (shown by the iodoform test), and propaldehyde (shown by the skatole test).

On distillation the liquid darkened and a small quantity of an aldehyde, b.p. 75° (*n*-butaldehyde) passed over. A trace of a white solid (paraformaldehyde?) separated at 90°. At 100° a few drops of water distilled. At 103° isobutaldehyde and at 128° caproic aldehyde were isolated in small quantities. Above 130°, decomposition set in rapidly; distillation ceased at 150°. The residue, small in quantity, was black and viscous and possessed a rancid odour; it was soluble in water yielding a strongly acid solution which did not give an aldehyde reaction with Schiff's reagent. Since *n*-hexane and the lower fatty acids distil without decomposition, other compounds such as dibasic, hydroxy or ketonic acids and lactones were probably present.

The upper layer of the residue had a volume of 142 c.c. On fractionation of an aliquot portion, *n*-hexane corresponding to 129 c.c. on the whole was recovered. It contained small quantities of formaldehyde, higher aldehydes, and acid. A dark brown, viscous liquid remained; this possessed a fruity odour, was slightly acid and insoluble in water. On further heating small fractions corresponding to butyric, valeric, and *n*-hexoic acids were obtained. The greater portion, however, remained as a residue, boiling up to 250°, when decomposition occurred. There would seem to be present, from the boiling point, hexyl hexoate. It is known that this ester is produced when hexyl alcohol is oxidised with acid bichromate solution to hexoic acid (Franchimont and Zincke, Annalen, **163**, 197), and a similar reaction would seem to have occurred here. During the oxidation the acid may have combined, as formed, very rapidly with the alcohol present, but more probably hexoic aldehyde is produced and undergoes simultaneous autoxidation and reduction to the alcohol and the acid, which combine *in statu nascendi* to the ester (*cf.* the Cannizzaro reaction).

A portion of the upper layer of the residue in the refluxing flask was allowed to stand over saturated sodium bisulphite solution for some days, when long, thin, rod-like crystals were deposited. These crystals were distilled with dilute sulphuric acid; the distillate, when treated with iodine and alkali, gave iodoform, showing that the sodium bisulphite compound of acetaldehyde had been obtained.

Before the various distillations described above were carried out, the total residue in the reaction flask was agitated and an aliquot portion of the temporarily homogeneous emulsion produced was withdrawn and examined quantitatively for formaldehyde, higher aldehydes, and total acidity. The wash waters in the bubblers were made up to a standard volume, and similar determinations performed on an aliquot portion.

The following are the complete results:—

Total volume of ozone reacting, 493·5 c.c. at N.T.P.

Total volume of hexane volatilised=approximately 1000 c.c. of vapour at N.T.P.

Total volume of monobasic acid recovered (c.c. vapour at N.T.P.)=95·4.

Total volume of formaldehyde (c.c. vapour at N.T.P.)=38·3.

Total volume of monoaldehydes other than formaldehyde (c.c. vapour at N.T.P.)=227·0.

Total volume of CO_2 (c.c. N.T.P.)=29·5.

The data provided under (2) in the subjoined table summarise the results of the experiment. For the purpose of comparison the results of another experiment (1) have also been tabulated.

Expt.		1.	2.
ume of air employed in litres		439·0	129·0
e of passage of air		1 litre in 3 mins.	1 litre in 3 mins.
ation of expt.		22 hrs.	11 hrs.
O_3 in air current (by vol.)		0·088	0·51
e of contact of ozone and hexane (mins.)		1·8	1·7
ozone consumed		96·4	74·6
obasic acid obtained per c.c. of O_3 applied, as c.c. vapour at N.T.P.	in hexane		
	in residue	0·12	0·13
	in wash waters	0·015	0·015
$_2O$ obtained per c.c. of O_3 applied, as c.c. of vapour at T.P.	in hexane		
	in residue	0·033	0·035
	in wash waters	0·028	0·023
O_2 obtained		Trace	Trace
no-aldehydes obtained per c.c. of O_3 applied in c.c. apour at N.T.P.	in hexane		
	in residue	0·15	0·311
	in wash waters	0·006	0·013

It will be observed that an increase in the per- ntage of ozone in the air stream enhances the yield higher aldehydes. Further, a higher concentration ozone leads to the production of relatively larger ounts of the gaseous oxidation products.

Discussion of results.—In all the experiments st of the monobasic acid formed remained in the ction flask, and the quantity was of the order of ·5 c.c. of monobasic acid vapour per c.c. of ozone plied.

The formaldehyde isolated was divided almost ually between the reaction flask and the washing ain. The quantity obtained increased somewhat th the percentage of ozone in the air or oxygen.

The greater part of the ozone and hexane con- med was recovered as higher monoaldehydes her than as formaldehyde. The major portion these aldehydes remained in the reaction flask. om a study of the quantity of hexane volatilised d of the quantity of ozone consumed, it is clear at much of the hexane passed through the apparatus changed. Comparison of the volumes of ozone nsumed with the quantities of aldehydes and acids tained show that the following reactions probably curred :—

$$_6H_{14}+7O_3=3C_{n-1}H_{2n-1}CHO+3C_{m-1}H_{2m-1}CHO +6O_2+3H_2O \text{ (where } m+n=6\text{), and}$$

$$C_pH_{2p-1}CHO+O_3=C_pH_{2p-1}CO_2H+O_2.$$

these equations represent the only reactions curring, then 7/6 times the volume of the alde- des+13/6 times the volume of the acid obtained, ould equal the volume of ozone consumed. Actually e figure is 502·55 c.c. as against 493·5 c.c. Evi- ntly in some of the oxidising actions the three oms of the ozone molecule were active.

A number of experiments with percentages of ozone rying from 0·09 to 1·72 gave very similar results regards the amount of the products obtained r c.c. of ozone reacting. That this similarity rsists, even with very low concentrations of ozone, ows that the oxygen of the air takes little or no rt in the oxidation.

Summary.

The products obtained by the action of ozone on iling *n*-hexane are as follows :—

) *Aldehydes.*—Formaldehyde, acetaldehyde (in rela- tively large quantities), and the higher aldehydes to hexoic.

) *Acids.*—Probably all up to hexoic (this present in greatest quantities).

(3) *Esters.*—Primarily hexyl hexoate (the presence of these compounds cannot be considered as definitely proved).

(4) Traces of water, carbon monoxide and dioxide.

The aldehydes of higher molecular weight than acetaldehyde are not found in any quantity, owing to the readiness with which they are oxidised to the corresponding acids, and perhaps owing to the for- mation of esters from them.

Acetaldehyde appears to be one of the chief products ; the hexane molecule, once attacked, apparently breaks down with ease.

This work was carried out on behalf of the Depart- ment of Scientific and Industrial Research, to whom we are indebted for permission to publish these results.

NOTE ON THE ACTION OF BROMINE ON *n*-HEXANE.

BY E. W. BLAIR, D.I.C., B.SC., A.I.C., W. LEDBURY, M.SC., A.I.C., AND T. S. WHEELER, B.SC., PH.D., F.R.C.SC.I., F.I.C.

In the authors' experiments on the action of ozone on *n*-hexane (*cf.* page 287 T), a bubbler containing bromine with a small quantity of water was attached to the end of the absorption system, to determine whether any unsaturated hydrocarbons were pro- duced. As the experiment progressed this bromine was gradually decolorised and finally two layers of liquid remained, the lower nearly colourless and the upper straw-coloured. A quantity of yellow crystalline solid was also observed.

The latter was filtered off and shaken with ether. A portion dissolved, and on evaporating the ether yielded white prisms, which, on recrystallisation from pure hexane, had m.p. 87°, b.p. 219°, and appeared to be identical with *p*-dibromobenzene. This was confirmed : (1) by analysis ; (2) by the fact that the addition of pure *p*-dibromobenzene gave no depression of the melting point ; (3) by conversion on nitration into 2.5-dibromonitrobenzene.

The portion insoluble in ether when washed with water, dried, and recrystallised from benzene, in which it was slightly soluble, yielded needles, m.p. 212°. Mixed with *trans*-benzene hexabromide, pre- pared by the action of sunlight on a mixture of bromine and benzene, no lowering of the melting point was observed.

The two layers of liquid were separated and ex- amined. The lower proved to be water. The upper was shaken with 0·5% caustic soda until colourless, and then extracted with ether. The extract was dried and the solvent evaporated. White crystals, which proved to be *p*-dibromobenzene, were obtained. No other products were isolated. In one experiment

about 5 g. of *p*-dibromobenzene and 1 g. of *trans*-benzene hexabromide were produced.

In order to determine if the products were formed by the action of bromine on the *n*-hexane carried through the apparatus, or on some of its oxidation products, blank experiments were performed in which *n*-hexane, three times fractionated (fraction collected boiling within 0·2°), was volatilised into bromine in a current of nitrogen, the same apparatus being used. Identical products were obtained. In these control experiments, and in those with ozone, much of the hexane passed through unattacked; a quantity of the bromine, too, was volatilised.

When benzene was substituted for hexane and a similar procedure adopted, *p*-dibromobenzene and *trans*-benzene hexabromide were again formed and in similar proportions. The rate at which they were produced, however, differed very little from their rate of formation from hexane, so that with the latter the presence of the benzenoid compounds in quantity in the bromine bubbler cannot have been due to any slight trace of the aromatic hydrocarbon in the hexane.

The above results therefore seem to indicate an action, hitherto unobserved, of bromine on *n*-hexane. No ring compounds, as far as we can trace, are reported in the literature as having been obtained by the action of bromine on *n*-hexane; the nearest analogous result is the production of hexabromobenzene, C_6Br_6, from secondary hexyl iodide and excess of bromine by heating under pressure at 220° (Ber., 11, 2247). The conditions necessary for this new reaction appear to be the presence of excess of bromine and of the hexane as a very dilute vapour. The direct action of liquid bromine on liquid *n*-hexane yields a liquid dibromohexane, b.p. 211° (Jahresber., 1862, 411). This result we have confirmed.

The mechanism of the reaction is not clear. Since benzene volatilised into bromine by means of nitrogen yields results identical with those given by hexane, it is possible that cyclohexane and then benzene are formed by oxidation of *n*-hexane by the bromine, and that the benzene is then brominated, by the great excess of bromine, to the hexabromide and the dibromo compound.

We hope further to investigate this phenomenon by allowing the vapours of benzene and *n*-hexane to mix; also, by cooling the gas coming from the bromine bubbler, to attempt to condense benzene or cyclohexane. Replacement of bromine by other oxidising agents, such as nitric acid, is contemplated.

We desire to express our thanks to the Department of Scientific and Industrial Research, for permission to publish this note.

.l. XLIII., No. 38] [September 19, 1924.

HE CAUSE OF THE LOW YIELD OF ALCOHOL ON FERMENTATION OF MOLASSES.

D. N. GUPTA, M.SC., H. D. SEN., M.SC., AND E. R. WATSON, M.A., D.SC.

This investigation was undertaken at the suggestion Mr G. H. Dickson, Managing Director of the Indian stillery Co., Cawnpore, who showed that the yield alcohol from the fermentation of molasses was ways considerably less than that expected from analysis of the molasses. He pointed out that low yield was probably not due to bad conditions fermentation, bacterial infection, etc., because in same distillery the yield of alcohol from *mohua* wers was much nearer to that expected from alysis. He also stated that the spent wash from lasses was able to reduce a considerable amount of hling's solution.

The object of this investigation was to ascertain cause of this low yield of alcohol and if possible find a means of improving the yield.

This low yield of alcohol from molasses is well own (see Allen's "Commercial Organic Analysis," ed., vol. 1, p. 357). The reducing power of nt wash is also known. In the "Chemists' Year ok," 1920, vol. 2, p. 866, for the determination invert sugar there is given a correction for non-ar substances which reduce Fehling's solution, principle being to ferment away sugars with wer's yeast and determine the reducing power after mentation. Harker (J. 1906, 831) came to conclusion that the non-fermentable reducing stances, returned as reducing sugar in the analysis molasses, and left in the spent wash, were not ficient to account for the low yield of alcohol, did these substances inhibit the complete fer-ntation of the sugars. In his opinion some stance returned as sucrose both by optical and uction methods was destroyed during fermentation hout giving any alcohol, even under conditions ing a very good yield of alcohol from sucrose.

Fermentation experiments.

All our experiments were made on a sample of lasses left in the manufacture of sugar from lian *ghur*. It gave the following figures on alysis: Reducing sugars 17·8%; sucrose (by rget's process) 37·4%; other organic matter n sugars) 14·6%; ash 6·5%; water 23·7%.

For analysis, the molasses solution was purified treatment with normal lead acetate, the excess lead was removed by disodium phosphate or hrogen sulphide, and the cupric reduction method lumetric and gravimetric) and polarimetric method e employed for determining sugar, the inversion ng effected by invertase in preference to acids. reducing sugars were determined by the cupric uction method and the sucrose by the polari-tric method, using Clerget's formula for calculation. The total sugar as reducing sugar was obtained by adding the amount of reducing sugars and the equivalent of the sucrose. The total sugar as reducing sugar was also determined direct by the cupric reduction method, the inversion being effected by invertase. The two methods gave 57·2 and 56·8% respectively, and the mean, 57·0%, was taken as the percentage of reducing sugar in the molasses. As pointed out by Harker (*loc. cit.*), the amount of reducing sugar returned is higher—viz., 59·3%—if the inversion is effected by acid.

A. Large scale fermentation. The weight of molasses used was 2545 kg., the volume of wash 1732 litres. Initial sp gr. 1·0491, final sp. gr. 1·0132. 500 c c of wash were distilled, and the distillate was made up to 500 c c. The alcoholic distillate had d 0·9935. 2545 kg of molasses contain sucrose and reducing sugars equal to a total of 1450 kg. of reducing sugars which, according to Pasteur, should yield 718 kg. of alcohol. The actual yield was 620 kg, or 86·3% of Pasteur's maximum practical yield. (Figures supplied by the Indian Distillery Co.)

B. Semi-large scale fermentation —Molasses used 17·24 kg. Initial sp. gr of wash 1·054, final 1·018. Volume of alcohol obtained, 4·2 litres of d 0·825 and 2·5 litres of d 0·945. 17·24 kg of molasses contain the equivalent of 9·82 kg. of reducing sugars which, according to Pasteur, should yield 4·86 kg of alcohol. The actual yield was 3·97 kg. of alcohol or 81·6%

C. Laboratory fermentation.—All precautions were taken to sterilise the molasses by boiling and dissolving in boiled distilled water. The wort was pitched with active yeast obtained from the Indian Distillery Co., and fermentation was carried out at 33°–35° in previously sterilised bottles, the mouths being closed by cotton-wool.

Molasses used, 140 g., volume of wash, 760 c c.; 0·5 g. of ammonium sulphate and 0·2 c c. of concentrated sulphuric acid were added.

Initial sp. gr. 1·048 to 1·052; volume of active yeast solution added, 150 c c.; total volume of fermented wash, 910 c.c.; final sp. gr. 1·016 to 1·020; volume of active wash reserved for next batch 150 c c.; volume of wash distilled, 760 c.c.

A series of eight experiments was carried out. The yield of alcohol obtained in each experiment is recorded in column 2, the yield expressed as percentage of Pasteur's maximum practical yield in column 3. The reducing power of the spent wash was determined in each experiment and the equivalent of reducing sugar is recorded in column 4. In column 5 is given the corrected value for sugar in the molasses, obtained by subtracting the amount of reducing substance in the spent wash from the original figure for reducing sugars in the molasses, and in column 6 is given the yield of alcohol reckoned from the corrected value for sugar in the molasses, and expressed as percentage of Pasteur's maximum practical yield.

Journal of the Society of Chemical Industry.

No. of expt.	Yield of alcohol g.	Alcohol as % of max. yield	Reducing power of spent wash.	Sugar in molasses (Corr.)	Yield of alcohol from corrected value.
1	32.4	82.0	12.1	67.4	99.7
2	33.1	83.8	10.8	69.0	99.0
3	31.7	80.2	11.6	68.2	97.9
4	32.5	82.3	12.0	67.8	98.9
5.	32.9	83.3	10.5	69.3	98.0
6.	33.6	85.1	10.2	69.6	99.6
7.	31.0	78.5	12.8	67.0	95.1
8.	33.0	83.5	10.6	69.2	98.4

These figures show that the reducing substance left in the spent wash entirely accounts for the low yield of alcohol from the molasses.

This result is in direct contradiction of that obtained by Harker (*loc. cit.*) He does not mention the source of the molasses examined, but it contained more ash and less reducing sugars than our sample, and, especially, it gave much less reducing substance in the spent wash viz., 2.46% on the weight of molasses, whilst our sample gave 8.1%.

Nature of the reducing substances left in the spent wash.

Pentoses. It appeared possible that the reducing substances left in the spent wash might be sugars such as pentoses unfermented by ordinary yeast. The original molasses gave the furfural test for pentose and the spent wash gave a small quantity of osazone which, on purification melted at 156°–158° (*cf.* arabinosazone, m.p. 158°, xylosazone, m.p. 158°).

Pentoses were determined in the original molasses by the method of Günther, de Chalmot, and Tollens (Ber., 1891, **24**, 3575) and found to be present to the extent of 1.2%.

Glutose. This unfermentable sugar has been found in sugar-cane molasses in amounts varying from 1 to 5%, as a result of the action of the lime used in clarification upon the invert sugar of the juice. Not being fermentable it is found as a constituent of the vinasse from molasses distilleries (Pellet, Bull. Assoc. Chim. Sucr., **16**, 1181; **19**, 834; Browne, "Handbook of Sugar Analysis," p. 629). It was thought at first that the reducing substances present in the molasses and spent wash under investigation might be chiefly glutose, especially as the spent wash is optically inactive and aqueous solutions of glutose are said to show no perceptible optical activity. But according to the literature glutose forms an osazone, and this was confirmed by preparing a sample of glutose, which gave a good yield of osazone, crystallising in yellow, lustrous, silky needles, m.p. 181°–182°. But, as the spent wash gives only a very small yield of osazone, of which the melting point corresponds to that of a pentosazone, it cannot contain any appreciable quantity of glutose.

Organic acids. The reducing properties of the spent wash cannot be due to any ordinary organic acids with reducing properties, as these are all precipitated by normal lead acetate, whereas this reagent does not remove the reducing substances from the spent wash.

Gums. A good deal of the dissolved matter is precipitated from the spent wash by strong alcohol, and, conversely, a good deal of solid is left on exhaustively extracting with alcohol the residue obtained by evaporating the spent wash to dryness. The reducing power resides chiefly in the fraction insoluble in alcohol—*e.g.*, 100 g. solid matter gave 57.5 g. of residue insoluble in alcohol and 42.5 g extracted by alcohol; reducing substances in the insoluble residue (reckoned as reducing sugar) 15.6 g.; in the substance extracted by alcohol 4.4 g. The substance insoluble in alcohol was oxidised by nitric acid (*d* 1.2) and gave a good yield of mucic acid—viz., 100 g. gave 12.5 g. of crude mucic acid which, on recrystallisation gave 3 g. of pure mucic acid melting at 215°–216° and a second crop of 2.6 g. which almost entirely melted below 220°. This large yield of mucic acid proves that the reducing properties of the spent wash are chiefly due to a gum of the galactan type. In order to obtain further proof of this the spent wash was hydrolysed with 5% sulphuric acid for 18—24 hours. Some increase in reducing power was at first observed, but after prolonged boiling the reducing power actually decreased. Even after this protracted hydrolysis the bulk of the gum remained unchanged, as was seen by its insolubility in alcohol. A portion of the hydrolysed spent wash, 2.5 g of reducing substance, yielded 0.5 g of crude osazone which was fractionally crystallised from acetone. Only one pure osazone could be isolated from it; this melted at 192°—193° and was, therefore *galactosazone*. The initial increase in reducing power followed by eventual decrease can be explained on the assumption that the gum is partly of the galactan and partly of the xylan type and on hydrolysis it gives galactose and pentose, which latter is decomposed by protracted boiling with acid, giving furfuraldehyde.

The occurrence of such a gum in cane-juice, *ghur*, or molasses has not been previously described. Heriot ("Manufacture of Sugar from the Cane and Beet," pp. 128, 134) mentions the occurrence of xylan in sugar-cane and juice. But, as xylan is precipitated by lead acetate and, moreover, is quickly hydrolysed on heating with dilute hydrochloric or sulphuric acid (Browne, *loc. cit.*, p. 553), it cannot be the reducing substance which we have found in the spent wash, which is not precipitated by lead acetate and is very resistant to hydrolysis. Moreover, xylan would not yield mucic acid on oxidation.

Other gums which are mentioned as occurring in cane-juice are dextran and levan produced by the action of bacteria. But these substances yield dextrose and lævulose on hydrolysis and would not give mucic acid on hydrolysis.

Conclusion.

(1) This investigation has shown that in molasses prepared from Indian *ghur*, the low yield of alcohol on fermentation is almost entirely due to a gum, which on account of its reducing properties is returned as reducing sugar in the analysis of molasses. This gum is very resistant to acid hydrolysis and yields no dextrose or lævulose on protracted acid hydrolysis. It gives a good yield of mucic acid and is, therefore partly of the galactan type. It may be mixed gum of the galacto-xylan type.

It is intended to ascertain whether this gum could be used as a substitute for other gums which are employed as mucilage or in textile printing etc.

THE AMINO-NITROGEN OF WOOL IN RELATION TO CHLORINATION.

BY S. R. TROTMAN AND C. R. WYCHE.

The reactions which take place during the chlorina-on of wool are obscure and difficult to investigate, it it is supposed generally that the first action is to roduce chloramines, of the type R·NHCl or CO·NHCl, whilst further treatment results in e breaking down of the keratin molecule into simpler lorinated compounds and sulphuric acid. Meunier nd Latreille (Chim. et Ind., 1923, **10**, 636 642) ggest that stable chloramines are formed and that e hydrochloric acid thereby produced is fixed by on-chlorinated amino compounds, forming sub-ances of the type R·CO·NHR,HCl. It must be bserved that, if the keratin molecule is built up in e manner of a polypeptide, the number of free NH_2 roups capable of reacting with chlorine must be omparatively small. No direct evidence appears to ave been published concerning the amount of mino-nitrogen present in wool, although various bservers have determined the percentage of nitrogen ordinary and deaminated wool. During the course f some investigations upon the "unshrinkable" nish, it became desirable to try to determine both he amount and nature of the amino groups present wool, by direct measurement of the nitrogen volved. The following method was adopted.

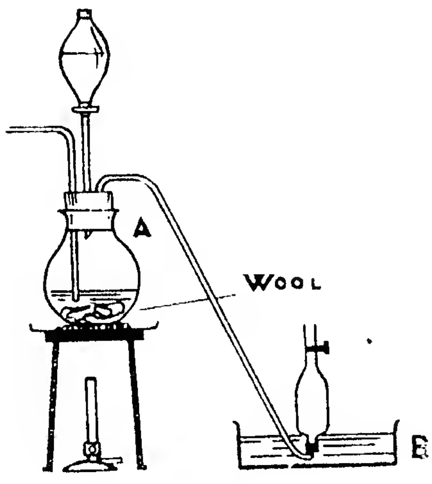

Fig 1.

A weighed piece of dry, purified webbing was placed n flask, A (Fig. 1), together with some water. The ontents of the flask were boiled to expel occluded air nd the flask was then connected, as shown, with a rbon dioxide generating apparatus, a tap funnel, nd a delivery tube dipping beneath the surface of odium or potassium hydroxide solution in B.

The tap funnel having been closed, the air was completely displaced by carbon dioxide. A solution of sodium nitrite in hydrochloric acid was then introduced by means of the tap funnel.

If any amino groups attached to aliphatic residues are present in wool, there should be an evolution of nitrogen at the ordinary temperatures. To expel this, a slow stream of carbon dioxide was passed through the apparatus for about three hours. The gas collected in the receiver was allowed to stand in contact with potassium hydroxide for some time, to free it from carbon dioxide. It was then transferred to a pipette, measured, and analysed, nitric oxide and oxygen being removed successively by means of ferrous sulphate and pyrogallol. The diazotisation of wool is a slow process, at the ordinary temperature, requiring at least 24 hours. After collecting any nitrogen formed by decomposition of aliphatic amino groups, the fabric was allowed to soak in the nitrous acid solution for from one to two days. It was then removed, washed with water, replaced in the flask, and the air again expelled by carbon dioxide. Cuprous chloride solution was then run in, through the tap funnel, and the contents of the flask were boiled gently to expel the nitrogen. The last traces were again swept out by means of carbon dioxide. The gas collected was analysed as before. The results of these experiments proved, quite conclusively, that wool contains amino groups attached to both aliphatic and aromatic residues. Several different kinds of wool were tested, and in every case there was an immediate liberation of nitrogen, followed by a further evolution when the diazotised product was boiled with w. ter or cuprous chloride solution. The percentages obtained, however, were not constant.

Some figures are given in the following table:—

Expt. no.	% N liberated in the cold.	% N liberated on boiling.	Total % N.
1	0·257	0·304	0·561
2	0·378	0·170	0·548
3	0·257	0·130	0·387
4	0·190	0·236	0·426

It was found, subsequently, that the azo compound of wool is decomposed slowly during the process of diazotisation and that the percentage of nitrogen obtained, on boiling, depended upon the interval between the first and second parts of the experiment. An experiment in which arrangements were made to prevent loss due to this cause gave for the total amino-nitrogen 0·785%. But the manipulation was very difficult, since a large volume of nitric oxide was also produced. Further tests are being made. In the last case the total nitrogen present in the original and deaminated wool was determined. The loss was 0·356%, *i.e.*, less than the total amino-nitrogen present. This difference agrees with that obtained by E. R. Trotman (J. Soc. Dyers and Col., 1924, 40, 77), but is much less than that given by Benz and Farrell (J., 1897, 406), namely from 0·1 to 1·2%. Kann's statement (J., 1914, 251) that no amino groups are present may be referred to, whilst Gebhard

D

(J., 1910, 640) says that no nitrogen is given off when diazotised wool is boiled. The fact that the total amino-nitrogen is greater than the difference between the percentage of nitrogen present in ordinary and deaminated wool must indicate that nitrosamines, of the type R·N(NO)R′, have been formed from imino groups. This is important, because the Liebermann test for imino groups is not applicable to keratin, after diazotisation and deamination, owing to secondary reactions disguising the colour. If wool contains as much as 1% of amino-nitrogen this would be quite insufficient to account for the chlorine which is absorbed during chlorination, as will be seen later. Hence it appears unlikely that the amino groups play a very important part in the reactions concerned. This is indicated also by the following experiments.

(1) Several specimens of knitted fabric were diazotised and deaminated by prolonged heating at a low temperature. It was found that deamination did not produce structural damage such as is associated with badly chlorinated samples (*cf.* Trotman, J., 1922, 219 T). The shrinkages of the original and deaminated fabrics were exactly the same; the tensile strength and elasticity were also unaltered. Thus in the case of a yarn:—

	Elasticity.	Tensile strength
Original yarn	19·2 ..	7·10
Deaminated yarn .. .	20·6 ..	7·31

When deaminated woollen fabrics are chlorinated they become unshrinkable. The fabric is neither more nor less sensitive to the treatment, the structural damage produced being practically the same in both cases.

(2) The total chlorine absorbed by ordinary and deaminated wool is practically the same, namely, from 24 to 35%, and in both cases the rate of absorption is almost identical. When wool or deaminated wool is treated with chlorine, there is, at first, a very rapid disappearance of chlorine, followed by a slow and gradual absorption. Thus, the curve consists of two distinct portions (Fig. 2).

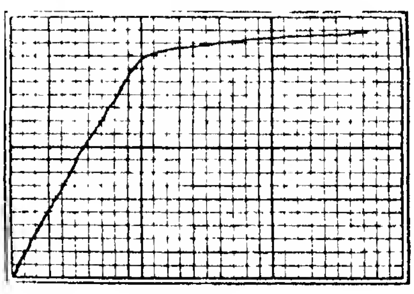

Fig. 2.

This appears to indicate that both adsorption and chemical action take place, at first simultaneously, and after adsorption has ceased, chemical action only. These points will be dealt with fully in a later paper, but the following experiments were made with the object of separating the total chlorine adsorbed and that which enters into chemical combination.

A purified knitted fabric was soaked in excess of chlorine water till absorption ceased. It was then washed several times with an acidified solution of hydrogen peroxide to remove adsorbed chlorine. It is known that the combined chlorine of chloramines is not liberated by hydrogen peroxide. After thorough washing, the residual chlorine was determined by boiling a weighed piece of the fabric with fuming nitric acid in the presence of silver nitrate. The experiment was then repeated with the same fabric after diazotisation and deamination. The results were:—

	% of combined chlorine on dry fabric No. 1.	No. 2.
Original fabric	6·6 ..	5·3
Deaminated fabric ..	6·4 .	5·7

After treatment with hydrogen peroxide, the fabric still liberated iodine from potassium iodide in the presence of an acid. This power was only destroyed very gradually by prolonged boiling with water. When wool is washed, after chlorination, with cold water, adsorbed chlorine is retained even after 24 hours' continuous washing. It is expelled by boiling with water. In one experiment, after washing in a stream of running cold water for 24 hours, the fabric was boiled with water four times for half an hour. It still liberated iodine from potassium iodide. The residual chlorine was in two different experiments (1) 0·6% and (2) 0·7%. It is evident that these chlorine compounds must be comparatively stable (*cf.* Meunier and Latreille, *loc. cit.*).

It has been shown already (Trotman, *loc. cit.*) that during the chlorination of wool, both nitrogen and sulphur are dissolved, the latter as sulphuric acid. The following confirmatory experiments have been made.

Pure cashmere wool was soaked for 24 hours in chlorine water. The total quantity of chlorine absorbed was 22·1%. After filtration the filtrate contained dissolved sulphur 0·49% and dissolved nitrogen 1·11% on the weight of wool. The filtrate was boiled, for some time, to expel chlorine and then evaporated to dryness at a low temperature. The dry residue still reacted with potassium iodide. Its aqueous solution gave the biuret reaction and precipitated tannic acid. It was partly soluble in alcohol. When the alcoholic extract was evaporated to dryness the residue still liberated iodine from potassium iodide, as also did the insoluble portion.

Summary.

(1) Wool contains both aliphatic and aromatic amino groups.
(2) The total amino-nitrogen is probably about 0·7%.
(3) The total amino-nitrogen is greater than that lost by deamination. Hence probably imino groups are present.
(4) The Liebermann reaction gives inconclusive results with wool.
(5) Ordinary and deaminated wool have the same shrinkage, elasticity and tensile strength, and absorb practically the same amount of chlorine.
(6) During chlorination of wool, chlorine is both adsorbed and enters into chemical combination.

(7) The prolonged action of chlorine gives rise to sulphuric acid and soluble nitrogen compounds. The latter contain firmly combined chlorine and are only decomposed by prolonged boiling. The chlorinated wool contains approximately 6% of chlorine which cannot be removed by means of hydrogen peroxide and which is only expelled by boiling.

PREPARATION OF ETHYL ACETATE AND ETHYL ACETOACETATE.

BY KENNETH CHARLES ROBERTS, M.SC.

Preparation and purification of ethyl acetate.

As a preliminary to the study of the preparation of ethyl acetoacetate, various methods of preparing and purifying ethyl acetate have been subjected to critical investigation.

Wade (Chem. Soc. Trans., 1905, **87**, 1656–1668) describes two continuous processes for the preparation of ethyl acetate. The "fast" process is claimed to give a product containing approximately 77% of ester, whilst the "slow" process, using equimolecular quantities of alcohol and acetic acid and only a very small quantity of sulphuric acid, is claimed to give a product containing 85% of ester. These yields appear surprisingly high when compared with those obtained in the ordinary way from mixtures of ethyl alcohol and acetic acid.

The residue in the "slow" process was observed to accumulate appreciably (*loc. cit.*, p. 1659); it is impossible to see how this can be so—the residue being mainly water—and yet the process still be truly continuous, *i.e.*, maintain its initial efficiency without a falling off in the percentage of ester in the distillate. The small quantity of sulphuric acid used must act largely as a catalyst, and there is, therefore, no apparent reason why the ordinary equilibrium for an equimolecular mixture of alcohol and acetic acid should be displaced to give a product containing 85% of ester as claimed by Wade.

As regards the "fast" continuous process, it may be assumed without appreciable error, that the residue after distillation is negligible. If then, the law of mass action is applied to a mixture containing originally $1\frac{1}{2}$ mols. of alcohol and 1 mol. of acetic acid, it may be shown that the distillate must contain about 18% of alcohol. This is not in agreement with Wade's figure of 12%, but agrees with the 19% observed in this investigation.

Wade's method of analysis is difficult to interpret, is intricate, and is also limited in its application owing to the proximity of the boiling points of the ternary and ester–water mixtures (70·3° and 70·45°, respectively, *loc. cit.*, p. 1666).

The practical investigation of the Wade processes is described below, and the yields of ester based on a different method of analysis are in both cases lower than those given by Wade, as was anticipated.

The following is a summary of the analytical method used in this investigation: A few grams of the crude ester are weighed out, and the free acid is titrated with standard alkali. The ester is then saponified with excess of 2*N* caustic soda, and the quantity of ester determined by titration with standard acid. The liquid is then distilled until all the alcohol has passed over, the quantity of alcohol being obtained by a density measurement. From the total alcohol thus obtained, that formed by saponification is deducted, and hence the original alcohol obtained. Water is obtained by difference.

The above method is not applicable in presence of a fifth constituent—*e.g.*, ether. Also, to ensure accuracy, density determinations must be made within 0·1° of the temperature for which the tables used are given. Duplicate analyses of a single distillate gave perfectly concordant results:—

Comparison of processes.

Summary of results.—

	100 c.c. glac. acetic with—	Wt. distillate.	% Composition		Wade's result.	B.p. range after treatment w. K_2CO_3		% Ester calc. on acetic acid.
A.	150 c.c. abs. alc. 5 c.c. conc. H_2SO_4. (Wade's "fast" continuous.)	204 g.	Acetic	2·5	—	70·1–	72°	92% (Excess alcohol).
			Ester	69·5	76·5			
			Alcohol	19·2	12·5			
			Water	8·8	11·0			
B.	100 c.c. abs. alc. 5 c.c. conc. H_2SO_4. (Wade's "slow" continuous.)	158 g.	Acetic	5·9				
			Ester	75·6	85·4	40% at 70°–	72°	77%
			Alcohol	7·7	8·6	30% at 72–	76°	
			Water	10·8	6·0			
C.	100 c.c. abs. alc. 20 c.c. conc. H_2SO_4. (Discontinuous process.)	150 g.	Acetic	4·3		Over 50% at 76°–	77°	83%
			Ester	86·8	—			
			Alcohol	4·7				
			Water	4·2				

Product C is thus the only one which lends itself readily to purification by fractionation.

When a further 200 c.c. of this mixture of acetic acid and alcohol was run into the residue in process B, the yield of ester fell to 73% by weight of distillate, thus showing that the process is not truly continuous, as had been anticipated from theoretical considerations.

In process C, the procedure is as follows: The mixture is heated under a reflux condenser on a water-bath for 10 minutes until equilibrium is attained, and the liquid then distilled from an oil-bath at 130°. The figure of 20 c.c. concentrated sulphuric acid is arrived at from thermo-chemical considerations.

It will be seen from the table that process A is wasteful of absolute alcohol, and the high alcohol content of the product makes purification very difficult. This process is, therefore, eliminated as a profitable source of ethyl acetate. Process B is much more efficient, but less so than process C, which lends itself very readily to the method of purification elaborated below. A detailed comparison of processes B and C in this connexion is given later.

Method of purification.

Wade mentions (*loc. cit.*, p. 1668) that alcohol impurity may be removed by repeated shaking with and distillation from water, but no data are given. This principle was adopted, and the following results were obtained:—

	Original composition	Water ratio 2:1 One distillation	Water ratio 2:1 Two distillations.	Water ratio 4:1 One distillation.
Ester	69·5%	86·8%	90·2%	89·1%
Alcohol	12·2%	6·8%	2·0%	4·7%
Water	8·8%	6·4%	7·8%	6·2%

Journal of the Society of Chemical Industry.

(J., 1910, 640) says that no nitrogen is given off when diazotised wool is boiled. The fact that the total amino-nitrogen is greater than the difference between the percentage of nitrogen present in ordinary and deaminated wool must indicate that nitrosamines, of the type R·N(NO)R', have been formed from imino groups. This is important, because the Liebermann test for imino groups is not applicable to keratin, after diazotisation and deamination, owing to secondary reactions disguising the colour. If wool contains as much as 1% of amino-nitrogen this would be quite insufficient to account for the chlorine which is absorbed during chlorination, as will be seen later. Hence it appears unlikely that the amino groups play a very important part in the reactions concerned. This is indicated also by the following experiments.

(1) Several specimens of knitted fabric were diazotised and deaminated by prolonged heating at a low temperature. It was found that deamination did not produce structural damage such as is associated with badly chlorinated samples (*cf.* Trotman, J., 1922, 219 T). The shrinkages of the original and deaminated fabrics were exactly the same; the tensile strength and elasticity were also unaltered. Thus in the case of a yarn:

	Elasticity.	Tensile strength.
Original yarn	19·2	7·10
Deaminated yarn	20·6	7·31

When deaminated woollen fabrics are chlorinated they become unshrinkable. The fabric is neither more nor less sensitive to the treatment, the structural damage produced being practically the same in both cases.

(2) The total chlorine absorbed by ordinary and deaminated wool is practically the same, namely, from 24 to 35%, and in both cases the rate of absorption is almost identical. When wool or deaminated wool is treated with chlorine, there is, at first, a very rapid disappearance of chlorine, followed by a slow and gradual absorption. Thus, the curve consists of two distinct portions (Fig. 2).

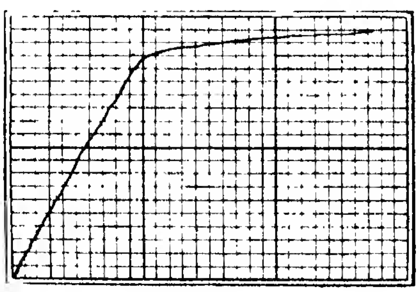

Fig. 2.

This appears to indicate that both adsorption and chemical action take place, at first simultaneously, and after adsorption has ceased, chemical action only. These points will be dealt with fully in a later paper, but the following experiments were made with the object of separating the total chlorine adsorbed and that which enters into chemical combination.

A purified knitted fabric was soaked in excess of chlorine water till absorption ceased. It was then washed several times with an acidified solution of hydrogen peroxide to remove adsorbed chlorine. It is known that the combined chlorine of chloramines is not liberated by hydrogen peroxide. After thorough washing, the residual chlorine was determined by boiling a weighed piece of the fabric with fuming nitric acid in the presence of silver nitrate. The experiment was then repeated with the same fabric after diazotisation and deamination. The results were:—

	% of combined chlorine on dry fabric. No. 1.	No. 2.
Original fabric	6·6	5·3
Deaminated fabric	6·4	5·7

After treatment with hydrogen peroxide, the fabric still liberated iodine from potassium iodide in the presence of an acid. This power was only destroyed very gradually by prolonged boiling with water. When wool is washed, after chlorination, with cold water, adsorbed chlorine is retained even after 24 hours' continuous washing. It is expelled by boiling with water. In one experiment, after washing in a stream of running cold water for 24 hours, the fabric was boiled with water four times for half an hour. It still liberated iodine from potassium iodide. The residual chlorine was in two different experiments—(1) 0·6% and (2) 0·7%. It is evident that these chlorine compounds must be comparatively stable (*cf.* Meunier and Latreille, *loc. cit.*).

It has been shown already (Trotman, *loc. cit.*) that during the chlorination of wool, both nitrogen and sulphur are dissolved, the latter as sulphuric acid. The following confirmatory experiments have been made.

Pure cashmere wool was soaked for 24 hours in chlorine water. The total quantity of chlorine absorbed was 22·1%. After filtration the filtrate contained dissolved sulphur 0·49% and dissolved nitrogen 1·11% on the weight of wool. The filtrate was boiled, for some time, to expel chlorine and then evaporated to dryness at a low temperature. The dry residue still reacted with potassium iodide. Its aqueous solution gave the biuret reaction and precipitated tannic acid. It was partly soluble in alcohol. When the alcoholic extract was evaporated to dryness the residue still liberated iodine from potassium iodide, as also did the insoluble portion.

Summary

(1) Wool contains both aliphatic and aromatic amino groups.
(2) The total amino-nitrogen is probably about 0·7%.
(3) The total amino-nitrogen is greater than that lost by deamination. Hence probably imino groups are present.
(4) The Liebermann reaction gives inconclusive results with wool.
(5) Ordinary and deaminated wool have the same shrinkage, elasticity and tensile strength, and absorb practically the same amount of chlorine.
(6) During chlorination of wool, chlorine is both adsorbed and enters into chemical combination.

(7) The prolonged action of chlorine gives rise to sulphuric acid and soluble nitrogen compounds. The latter contain firmly combined chlorine and are only decomposed by prolonged boiling. The chlorinated wool contains approximately 6% of chlorine which cannot be removed by means of hydrogen peroxide and which is only expelled by boiling.

PREPARATION OF ETHYL ACETATE AND ETHYL ACETOACETATE.

BY KENNETH CHARLES ROBERTS, M.SC.

Preparation and purification of ethyl acetate.

As a preliminary to the study of the preparation f ethyl acetoacetate, various methods of preparing nd purifying ethyl acetate have been subjected to ritical investigation.

Wade (Chem. Soc. Trans., 1905, 87, 1656–1668) escribes two continuous processes for the preparation f ethyl acetate. The "fast" process is claimed to ive a product containing approximately 77% of ster, whilst the "slow" process, using equimolecular uantities of alcohol and acetic acid and only a ery small quantity of sulphuric acid, is claimed o give a product containing 85% of ester. These ields appear surprisingly high when compared ith those obtained in the ordinary way from ixtures of ethyl alcohol and acetic acid.

residue in the "slow" process was observed t cumulate appreciably (*loc. cit.*, p. 1659); it is npossible to see how this can be so—the residue mainly water—and yet the process still be y continuous, *i.e.*, maintain its initial efficiency ithout a falling off in the percentage of ester in e distillate. The small quantity of sulphuric acid sed must act largely as a catalyst, and there is, herefore, no apparent reason why the ordinary quilibrium for an equimolecular mixture of alcohol nd acetic acid should be displaced to give a product ontaining 85% of ester as claimed by Wade.

As regards the "fast" continuous process, it may e assumed without appreciable error, that the esidue after distillation is negligible. If then, the w of mass action is applied to a mixture containing iginally $1\frac{1}{2}$ mols. of alcohol and 1 mol. of acetic cid, it may be shown that the distillate must ontain about 18% of alcohol. This is not in greement with Wade's figure of 12%, but agrees ith the 19% observed in this investigation.

Wade's method of analysis is difficult to interpret, s intricate, and is also limited in its application owing o the proximity of the boiling points of the ternary nd ester-water mixtures (70·3° and 70·45°, espectively *loc. cit.*, p. 1666).

The practical investigation of the Wade processes s described below, and the yields of ester based n a different method of analysis are in both cases ower than those given by Wade, as was anticipated.

The following is a summary of the analytical nethod used in this investigation: A few grams of he crude ester are weighed out, and the free acid is titrated with standard alkali. The ester is then saponified with excess of $2N$ caustic soda, and the quantity of ester determined by titration with standard acid. The liquid is then distilled until all the alcohol has passed over, the quantity of alcohol being obtained by a density measurement. From the total alcohol thus obtained, that formed by saponification is deducted, and hence the original alcohol obtained. Water is obtained by difference.

The above method is not applicable in presence of a fifth constituent—*e.g.*, ether. Also, to ensure accuracy, density determinations must be made within 0·1° of the temperature for which the tables used are given. Duplicate analyses of a single distillate gave perfectly concordant results:—

Comparison of processes.

Summary of results:—

	100 c.c. glac. acetic with—	Wt. distillate	% Composition		Wade's result	B.p. range after treatment with K_2CO_3		% Ester calc. on acetic acid.
A.	150 c.c. abs. alc. 5 c.c. conc. H_2SO_4. (Wade "fast" continuous.)	201 g.	Acetic	2·5		70·4°–72°		92% (Excess alcohol)
			Ester	69·5	76·5			
			Alcohol	19·2	12·5			
			Water	8·8	11·0			
B.	100 c.c. abs. alc. 5 c.c. conc. H_2SO_4 (Wade "slow" continuous.)	158 g.	Acetic	5·9		60% at 70°–72°		77%
			Ester	75·6	85·4	30% at 72°–76°		
			Alcohol	7·7	8·6			
			Water	10·8	6·0			
C.	100 c.c. abs. alc. 20 c.c. conc. H_2SO_4 (Discontinuous process.)	150 g.	Acetic	4·3	—	Over 70% at 76°–77°		83%
			Ester	86·8				
			Alcohol	4·7	—			
			Water	4·2				

Product C is thus the only one which lends itself readily to purification by fractionation.

When a further 200 c.c. of this mixture of acetic acid and alcohol was run into the residue in process B, the yield of ester fell to 73% by weight of distillate, thus showing that the process is not truly continuous, as had been anticipated from theoretical considerations.

In process C, the procedure is as follows: The mixture is heated under a reflux condenser on a water-bath for 10 minutes until equilibrium is attained, and the liquid then distilled from an oil-bath at 130°. The figure of 20 c.c. concentrated sulphuric acid is arrived at from thermo-chemical considerations.

It will be seen from the table that process A is wasteful of absolute alcohol, and the high alcohol content of the product makes purification very difficult. This process is, therefore, eliminated as a profitable source of ethyl acetate. Process B is much more efficient, but less so than process C, which lends itself very readily to the method of purification elaborated below. A detailed comparison of processes B and C in this connexion is given later.

Method of purification.

Wade mentions (*loc. cit.*, p. 1668) that alcohol impurity may be removed by repeated shaking with and distillation from water, but no data are given. This principle was adopted, and the following results were obtained:—

	Original composition	Water ratio 2:1 One distillation.	Water ratio 2:1 Two distillations	Water ratio 4:1 One distillation.
Ester ..	69·5%	86·8%	90·2%	89·1%
Alcohol	12·2%	6·8%	2·0%	4·7%
Water	8·8%	6·4%	7·8%	6·2%

Journal of the Society of Chemical Industry.

The loss of ester is thus very slight, and about 75% of the alcohol originally present is left behind in the flask at each distillation. Wade states (p. 1668) that only 30% of the alcohol is left behind after each distillation from water, but does not state the amount of water used.

The 2% of alcohol left after this treatment may, if desired, be readily removed by fractionation without serious loss of ester. It is also insufficient to interfere with drying processes to any extent. (Potassium carbonate and other agents are not completely effective in presence of much alcohol.)

The separation by distillation from water depends on the volatility of the alcohol in the alcohol water mixture (b.p. 78·15°) at the temperature of distillation of the ester-water mixture (70·45°). Hence, if the ester layer be first separated, and the aqueous layer containing practically all the alcohol be then distilled to recover its dissolved ester, an even better separation than the above should be obtained. This procedure, when tried, gave such favourable results, that it was adopted subsequently.

Application of method of purification to the Wade "slow" discontinuous and the continuous processes.

Summary of results: –

200 c.c. each alcohol and acetic acid with	Wt. of distillate	Ester in distillate	Yield on alcohol	Water ratio	Purification. Wt. ester boiling within 0·5°.*	% on original alcohol.
(1) 10 c.c. H_2SO_4 ('Slow' continuous)	313 g.	77·6%	79·1%	3 : 1	158 g.	62%
(2) 10 c.c. H_2SO_4 (Discontinuous)	328 g.	83·5%	89·5%	2 : 1	170 g.	57%

* After drying over potassium carbonate and fractionating three times.

All low-boiling residues, the bulk of which had an ester content of over 90%, were kept and worked up in the same way, so that loss of ester was reduced to a minimum.

The discontinuous process, therefore, gives a higher yield of ethyl acetate after treatment with water in the ratio of two to one, than does the slow continuous when water is used in the ratio of three to one. It is also more expeditious.

Summary.

Ethyl acetate is best prepared as follows: An equimolecular mixture of absolute alcohol and glacial acetic acid is heated under a reflux condenser with one-tenth its volume of concentrated sulphuric acid on the water-bath for 10 minutes, and then distilled from the oil-bath at 130°. The crude distillate is purified by shaking with twice its volume of water, separating the ester layer, and distilling the aqueous layer up to 72° for dissolved ester. The two portions of ester thus obtained are mixed, dehydrated over potassium carbonate, and fractionated. Ester of 98% purity, free from water, is then obtained in excellent yield by collecting the portion boiling at 76·15°–77·15° (1 mm. of mercury corresponds to a change in boiling point of 0·06°).

Final purification of the high-boiling ester was effected by heating it with phosphorus pentoxide (Inglis and Knight, Chem. Soc. Proc., 1907, 198) and then fractionating. The whole product distilled within 0·1°, and the bulk, as nearly as could be judged, at a constant temperature. This highly purified material was used in the subsequent work.

Preparation of acetoacetic ester.

The mechanism of the reaction in the synthesis of acetoacetic ester has never been fully explained, and it was thought that by carrying out a series of quantitative measurements of the yields obtained under a standard set of conditions, the condensing agent only being varied, further light might be thrown on the mechanism of the reaction; also that the ordinary laboratory preparation might be improved.

The ethyl acetate used throughout the following series of condensations was the constant boiling material prepared as described above. Caustic soda was excluded, as far as possible, in adding sodium by weighing out the required amount of clean metal in anhydrous ether, and rejecting the first and last portions of wire which emerged from the press, since they were generally somewhat tarnished. In each case 100 g. of ethyl acetate were condensed with 10 g. of sodium or the equivalent amount of other condensing agent.

Condensations were carried out as follows: –

(1) Ethyl acetate with metallic sodium.

(2) Ethyl acetate and sodium with varying percentages of alcohol.

(3) Ethyl acetate and sodium ethoxide.

(4) Ethyl acetate and sodamide.

Summary of results: –

Condensing agent	Time for reaction, hours	Yield of acetoacetate, g.	B.p. ranges of ethyl acetate-alcohol mixture.
Sodium . .	6 ..	Not obtainable	–
„ (wire) }*	2 ..	.. 18 ..	–
„ (powder) }†	1 .	.. 18 ..	–
„ ½% alcohol	1¾ .	.. 18 .	75·5°–76·5°
„ 1% „	1¼ .	. 19 ..	75°–76·5°
„ 2% „	1¼	. 23 .	74·5°–76·5°
„ 5% „	1½ ..	.. 24 ..	73·5°–76·5°
„ 10% „	1 .	12 ..	72°–76·5°
„ 5% „ and 1% water	¾ ..	trace	–
„ chloride	2 .	„ ..	–
Sodamide .	not observed	4 ..	–
Ethyl acetate A	1 .	.. 15 ..	not observed
„ „ B .	1½ ..	.. 22	74°–76·5°

* To exclude all trace of caustic soda, a piece of sodium was heated with ethyl acetate until all tarnish was removed. The liquid was then decanted, the sodium washed rapidly three times with ethyl acetate, and, finally, a further quantity of the latter added and the mixture heated under a reflux.

† It might be anticipated that prolonged heating would decrease the yield of acetoacetic ester owing to formation of by-products, but, within limits, this is seen not to be the case.

Ethyl acetate A is the crude material from the discontinuous preparation simply dehydrated with potassium carbonate and condensed with sodium. Taking the other results into consideration, it is evident that there is either a trace of water or too much alcohol present, and so the maximum yield is not obtained.

Ethyl acetate B is the crude material from the discontinuous preparation purified by one distillation from water as described above, and then dehydrated over potassium carbonate.

The above results show that the maximum yield f acetoacetic ester is obtained by condensing a ynthetic mixture of pure ethyl acetate and 5% f absolute alcohol with untarnished sodium wire. 'urthermore, when using the purest materials availble, the reaction between ethyl acetate and sodium s initially extremely slow, even at the boiling emperature, but later proceeds with increasing apidity. This is to be expected if even a minute race of alcohol or water is initially present, since his trace will react to produce more alcohol, either lirectly, in the case of a trace of alcohol, or by ormation of caustic soda and subsequent saponifying ction in presence of a trace of water. In addition, he yield using ethyl acetate and sodium only, is ower than when alcohol is present. It would, herefore, appear that sodium alone is ineffective is a condensing agent, though the actual mode of eaction of sodium ethoxide or sodamide is not as et definitely known (*cf.* Scheibler and Ziegner, Ber., 1922, **55**, B, 789).

The above observation is in direct opposition to hat of Tingle and Torsline (J. Amer. Chem. Soc. 908, **30**, 1875), but the validity of their conclusions s rendered doubtful on the following grounds: The yields obtained with different grades of ester ire not given, whilst accuracy with regard to the boiling point of the ethyl acetate used does not appear o have been rigidly observed. Moreover, a neutral eaction of the ethyl acetate to litmus is no test of he freedom of the ester from alcohol and water, he most likely impurities and the most important. Also, treatment with calcium chloride after phoshorus pentoxide appears ineffective, since calcium hloride is appreciably soluble in ethyl acetate and lecomposes it at the boiling point (Le Cann, Compt. rend., 1885, **100**, 40). Granted, however, that the ethyl acetate employed was pure, it is also allmportant that the sodium introduced should be ree from caustic soda. No mention is made of precautionary measures in this regard, but the claim s, nevertheless, made that sodium dissolves as eadily in pure ethyl acetate as when alcohol is present. In view of the results given above, this would not appear to be the case.

The progressive falling off in the yield between a condensing agent containing 5% of alcohol, and one consisting solely of sodium ethoxide would appear to be due to the accumulation of alcohol in the reaction mixture. An increasing quantity of alcohol in the reaction mixture would cause a displacement of the equilibria cited by Dieckmann (Ber., 1900, **33**, 2670) unfavourable to the formation of ethyl acetoacetate.

The present series of experiments has also established the best set of conditions under which to carry out the reaction as a laboratory preparation. This follows since ethyl acetate B (above) gives a yield comparable with the best obtainable from pure materials. The value of this observation is increased by the fact that ethyl acetate B is so readily prepared. Finally, the reason for low yields in the ordinary laboratory preparation is not, as is often stated in textbooks, the presence of appreciable quantities of alcohol, but rather the presence of small quantities of water or caustic soda.

In conclusion, the author wishes to express his indebtedness to Professor Inglis for his guidance during the course of this work.

THE RATE OF DISAPPEARANCE OF SULPHITES IN RAW MEAT.*

BY F. H. CAMPBELL, D.SC.

The Health Acts governing, *inter alia*, the manufacture and sale of foods in Australia, provide that all samples taken for analysis shall be divided into three parts by the official, who makes the purchase, and that of these one shall be retained by him for analysis by an umpire in case of any dispute. The Acts contain no direction as to the treatment of this sample and, in the case of materials such as meat, changes may occur which render its analysis useless. The addition of sulphites to raw minced or sausage meat is permitted but the amount must not exceed a quantity corresponding to 3·5 grains of sulphur dioxide per lb. Except in summer the temptation to use excess of preservative is small, so that almost all the samples are taken during warm weather. Before the sample can reach the umpire analyst a period of not less than a month must elapse, and experience has shown that meat kept in a sealed vessel at ordinary summer temperatures loses sulphite at a rapid rate. For example, the author found in a sample six weeks old only one-fortieth of the amount of sulphur dioxide reported to be present by the analyst who examined the fresh sample. In a recent case in Victoria the municipal analyst found the fresh sample to contain an amount of preservative in excess of that permitted, the author found 1·2 grains of sulphur dioxide per lb. in the month-old sample, and the umpire, whose sample was some six weeks old, found a slightly smaller amount. He added to his report a comment to the effect that the condition of the sample was such that it was impossible to judge of the amount originally present. The result was that the defendant was convicted and fined.

The outcome of this case was that the author was commissioned by the Master Butchers' Association of Victoria to investigate the rate at which sulphites disappear when admixed with raw meat and kept under different conditions in closed bottles.

The scope and details of the investigation are given below.

The meat used was freshly-minced lean beef to which a certain proportion of flour had been added; it yielded sulphur equivalent to 0·13 grain of sulphur dioxide per lb. of meat. Sodium sulphite, which

* Read at a meeting of the Sydney Section, May 14 1924.

yielded 11·9% of sulphur dioxide, was finely powdered and thoroughly incorporated with the meat by hand.

Approximately equal weights of treated meat were placed in clear, wide-mouthed bottles, and the glass stoppers, after insertion, were dipped into molten paraffin wax. Three sets of samples were exposed to diffused daylight and the ordinary fluctuations of temperature. The records kindly supplied by the Meteorological Department show that the mean temperature during the period under review was about 50° F. The fourth set of samples was kept in a refrigerating chamber.

At the end of each period a bottle of each set was opened and 50 grams of its contents were removed and analysed at once. The ordinary method was used, namely, liberation of sulphur dioxide in an atmosphere of carbon dioxide by means of 20% phosphoric acid, absorption of the gas in $N/10$ iodine, with a final weighing as barium sulphate.

The following results were obtained.

TABLE I.

Age of sample	SO_2 present (in grains per lb.) Mixture at room temperature 1 Grains	Loss %	2 Grains	Loss %	Mixture in refrigerator Grains	Loss %
Original (calc.)	2·72		5·65		2·72	
As bottled	2·42		5·52		2·42	
7 days	2·11	12·8	5·40	2·2	2·19	9·5
14 „	2·17	10·4				
28 „	2·13	12·0				
42 „			5·24	5·1	2·19	9·5

In the first sample at room temperature, some liquid had separated after 28 days; in the second sample moulds and gas developed after seven days, whilst after 42 days a muddy black liquid separated. In the mixture kept in the refrigerator, a slight amount of water had separated after 42 days, but there was no mould growth.

The development of mould in the mixture containing the greatest amount of preservative and the evidences of incipient putrefaction are attributed to the fact that the meat used in this set was exposed to the atmosphere for some hours before the mixture was made and bottled. A fourth set gave somewhat irregular results, owing to imperfect mixing, but they were confirmatory, in a general way, of the rest.

The results show that the rate of disappearance is greatest during the first seven days, but that, if the sample is kept in hermetically sealed vessels at a temperature not exceeding 50° F., there is but slight risk of disagreement between the results of reliable analysts even if the sample is as much as six weeks old. They show, further, that "freshness" as judged by the appearance and odour of the sample is no criterion of its suitability for analysis for preservative provided the temperature has not materially exceeded 50° F.

Effect of cooking. The amount of sulphur dioxide was determined in two samples before and after cooking, a weighed quantity of meat being fried with a weighed quantity of fat.

TABLE II.

Sample	SO_2 in raw meat Grs. per lb.	SO_2 in cooked meat Grs. per lb.	Loss. %	Time of cooking. Min.
Minced meat	3·60	0·08	97·8	20
Sausage	3·40	1·74	48·8	30

Mechanism of the change of sulphite in presence of meat.—No systematic attempt was made to elucidate the chemistry of the disappearance of sulphite, but it can be shown that if, as is most probable, sulphate is formed as the result of aerial oxidation, the penetration of raw meat by air is an exceedingly slow process under the conditions obtaining in these experiments. Autoxidation does not appear to occur (Sheinfield, Vilbrandt, and Withrow; Chem. and Met. Eng., 1921, **25**, 953). It was proved by actual measurement that the bottles contained two to five times as much oxygen as is necessary for the conversion of the whole of the sulphite present into sulphate.

Conclusions.

(1) Raw meat containing sulphite remains in a condition suitable for analysis for six weeks and probably longer, provided the temperature is kept sufficiently low.

(2) The suitability of a sample of meat for analysis cannot be judged by the odour and appearance, if it has been kept in cold storage.

(3) A Health Act which does not contain specific directions as to the storage of perishable samples is inequitable and should be amended.

RYLAMINE SALTS OF THE NAPHTHA-NESULPHONIC ACIDS. II.—THE SALTS α- AND β-NAPHTHALENESULPHONIC ACIDS.

R. H. FORSTER, D.SC., PH.D., F.I.C., AND C. M. KEYWORTH, M.SC., A.I.C.

In a previous paper (J., 1924, 165 T) we described arylamine salts of the 2.6- and 2.7-naphthalene-ulphonic acids and cited the literature on this ject. This communication embodies the results our work on similar salts of α- and β-naphthalene-phonic acids.

Fierz-David (J., 1923, 421 T) confirms that it is possible to prepare either the α or the β acid in a re state by sulphonation alone. He states that der the optimum conditions for the α acid, the oduct is a mixture of 96% of α and 4% of β acid, d under the optimum conditions for the formation the β acid, the product consists of 85% of β and % of α acid.

Mixtures of these acids may be separated by means their arylamine salts, the aniline, p-toluidine, and xylidine salts being particularly useful in this spect, and moreover, since the majority of these lts have well-defined melting points, the testing of e purity of the product is simple.

On the other hand, the sulphonic acids are conveni-t for precipitating and identifying small quantities unknown amines, as the various salts melt over a ide range of temperatures.

The α- and β-naphthalenesulphonic acids readily rm a series of well-defined salts with arylamines. he salts of the α acid are usually more soluble than e analogous salts of the β acid—usually about three mes as soluble at the ordinary temperature. This, owever, is not always the case; for example, the chloroaniline dichloroaniline, m-nitroaniline, p-tro-o-toluidine, and p-phenetidine salts of the α id have approximately the same solubility or are ss soluble than the corresponding salts of the β acid the ordinary temperature.

The salts were prepared by similar methods to those escribed in our previous paper, and in addition the ad salt of the α acid and the barium salt of the β acid ere also utilised, as it was found that in some cases here the hydrochloride of the amine was added to e sodium salt of the acid, the sodium salt of the acid variably separated out. In all cases molecular uantities of the base and acid, plus a slight excess of e base, were used. In the case of diamines, the lts usually consist of one molecule of the base and molecules of the acid. Basic salts are difficult to btain, the only one that was isolated being basic toluidine-β-naphthalenesulphonate.

In the case of substituted amines, the salts with he α acid have their melting points in the order p, , o, ortho being the highest. With the β acid, however, the order is m, o, p. The solubilities in water do not lend themselves well to such a generalisation, but in the cases of the toluidines, both the α acid and the β acid salts are in the order m, o, p.

The best solvent for all the salts was found to be water slightly acidified with hydrochloric acid. Ethyl alcohol can also, in certain cases, be used for purification.

Dissociation occurs in boiling aqueous solution, especially when the amine is volatile in steam, but this can be prevented by the addition of a little hydrochloric acid.

The titration and determination of solubility of the salts were carried out as described for the 2.6- and 2.7-naphthalenedisulphonic acids (*loc. cit.*). All the solubilities are recorded as parts by weight of salt in 100 parts by weight of solution, and all melting points are corrected. Where no melting point is recorded, the salt did not melt below 330°.

The α- and β-naphthalenesulphonic acids used in the investigation were given a preliminary purification, the α by recrystallisation from alcohol, and the β by recrystallisation from water. The following salts were prepared and studied :—

Aniline α-naphthalenesulphonate.—10 g. of sodium α-naphthalenesulphonate were dissolved in 40 c.c. of hot water and 8 c.c. of concentrated hydrochloric acid, and 6 c.c. of aniline were added. On cooling, crystals were quickly formed. When twice recrystallised from water, white leaflets were obtained, m.p. 183°, which were very readily soluble in hot alcohol. *Solubility, 1·58/100 at 15°; 0·4142 g. required 13·75 c.c. of $N/10$ NaOH = 99·9% theory.

Aniline β-naphthalenesulphonate, prepared as in the case of the α salt, was obtained as fine white needles, m.p. 269°. It can be easily recrystallised from alcohol, in which it is only sparingly soluble in the cold. Solubility 0·52/100 at 15°; 0·6432 g. required 21·3 c.c. of $N/10$ NaOH = 99·7% theory.

o-Toluidine α-naphthalenesulphonate.—White crystals readily recrystallised from water, m.p. 237°. Very soluble in boiling alcohol. Solubility 0·99/100 at 15°; 0·5490 g. required 17·4 c.c. of $N/10$ NaOH = 99·8% theory.

o-Toluidine β-naphthalenesulphonate.—Readily recrystallised from water or alcohol in the form of white, feathery needles, m.p. 213°. Solubility 0·47/100 at 16°; 0·5804 g. required 18·2 c.c. of $N/10$ NaOH = 98·8% theory.

m-Toluidine α-naphthalenesulphonate.—10 g. of sodium α-naphthalenesulphonate and 5 g. of m-toluidine were dissolved in 45 c.c. of hot water and 5 c.c. of hydrochloric acid. On cooling, a lower oily layer separated, but both layers crystallised on further standing. On recrystallisation white, silky needles were obtained, m.p. 195°—196°, which are readily soluble in hot water and alcohol. Solu-

* Solubility—100 parts by weight of solution contain 1·58 parts by weight of salt at 15°.

bility 0·68/100 at 12°; 0·4196 g. required 13·3 c.c. of N/10 NaOH = 99·8% theory.

m-Toluidine β-naphthalenesulphonate.—Readily recrystallised from hot water. Colourless plates, m.p. 205°. Solubility 0·39/100 at 15°; 0·716 g. required 22·2 c.c. of N/10 NaOH = 99·7% theory.

p-Toluidine α-naphthalenesulphonate.—25 g. of sodium α-naphthalenesulphonate were dissolved in 100 c.c. of water, and 16·7 g. of p-toluidine dissolved in 15 c.c. of hydrochloric acid and 50 c.c. of water were added. On cooling an emulsion was first formed, which soon separated into a greenish upper layer and a brownish lower oily layer. When nearly cold the lower layer solidified to a whitish stringy mass. It can be recrystallised from water or from ethyl alcohol, in which it is very soluble even in the cold; m.p. 181°. Solubility 1·38/100 at 15°; 0·4418 g. required 13·95 c.c. of N/10 NaOH = 99·5% theory.

p-Toluidine β-naphthalenesulphonate.—This salt was used for preparing pure β-naphthalenesulphonic acid. 47 g. of sodium β-naphthalenesulphonate were dissolved in 500 c.c. of hot water, the solution was filtered, and 20 c.c. of hydrochloric acid and 22 g. of p-toluidine were added. The crystals which separated on cooling, were washed with 100 c.c. of cold water, and had m.p. 211°–212°. On recrystallisation very pale yellow, fine needles, m.p. 221°, were obtained. Solubility 0·47/100 at 16°; 1·1236 g. required 35·3 c.c. of N/10 NaOH = 99·1% theory.

m-Xylidine α-naphthalenesulphonate.—10 g. of sodium α-naphthalenesulphonate, 7·2 g. of m-xylidine acetate, and 2 c.c. of hydrochloric acid were dissolved in 40 c.c. of hydrochloric acid. Two layers were formed, but on standing both crystallised. On recrystallisation white, glistening needles were obtained, m.p. 167°. This salt is best recrystallised from alcohol, in which it is very soluble. It does not recrystallise well from water and partly becomes an oil in boiling water. Solubility 1·20/100 at 15°; 0·4722 g. required 14·25 c.c. of N/10 NaOH = 99·3% theory.

m-Xylidine β-naphthalenesulphonate.—Sufficient hydrochloric acid was added to 10 g. of sodium β-naphthalenesulphonate and 7·2 g. of m-xylidine acetate in 40 c.c. of hot water to form a homogeneous solution. On cooling, two layers were formed, but the lower brown oily layer crystallised on standing. Recrystallised well from alcohol, in which it is sparingly soluble cold, m.p. 211°. Solubility, 0·27/100 at 10°; 0·5104 g. required 15·4 c.c. of N/10 NaOH = 99·2% theory.

α-Naphthylamine α-naphthalenesulphonate.—This salt was prepared by Ambler (J. Ind. Eng. Chem., 1920, **12**, 1081), who finds that it melts at 232° with decomposition. Our specimen was fairly soluble in boiling water, from which it was obtained in fine white leaflets, which melt at 229° to a light brown liquid and decompose about 275°. Solubility 0·23/100 at 12°; Wales (*ibid.*, 1922, **14**, 317) gives 0·31/100 at 25°. 0·4966 g. required 14·0 c.c. N/10 NaOH = 99·0% theory.

α-Naphthylamine β-naphthalenesulphonate.—10 g. of sodium β-naphthalenesulphonate in 100 c.c. of water were added to 6 g. of β-naphthylamine and 6 c.c. of hydrochloric acid in 150 c.c. water. A thick white precipitate was obtained whilst still hot. Recrystallised twice from boiling water, in which it is sparingly soluble, it yielded white, feathery crystals, m.p. 240° without decomposition. Ambler (*loc. cit.*) gives 240°—247° (decomp.). Solubility 0·11/100 at 12° (Wales gives 0·20/100 at 25°) 0·5392 g. required 15·4 c.c. of N/10 NaOH = 100·0% theory.

β-Naphthylamine α-naphthalenesulphonate.—10 g. of sodium α-naphthalenesulphonate were dissolved in 500 c.c. of hot water, and 6 g. of β-naphthylamine and 6 c.c. of hydrochloric acid in 500 c.c. of hot water were added. Crystals of m.p. 196°—199° separated in the hot solution. White plates, m.p. 193°—199°, were obtained when the mother liquor cooled. On recrystallisation, beautiful white plates were obtained, m.p. 200°–201°, very sharply and without decomposition (Ambler states that it blackens at 202° and melts at 211°). Solubility, 0·11/100 at 15° Wales gives 0·17/100 at 25°); 0·5232 g. required 14·85 c.c. of N/10 NaOH = 99·6% theory.

β-Naphthylamine β-naphthalenesulphonate.—6 g. of sodium β-naphthalenesulphonate in 500 c.c. of water were added to 4·5 g. of β-naphthylamine and 4 c.c. of hydrochloric acid in 700 c.c. water. A precipitate was obtained immediately. It was recrystallised from a large quantity of hot water, in which it is very sparingly soluble; m.p. 275°—276° Ambler gives m.p. 276°—279° (decomp.). Solubility 0·04/100 at 15° (Wales, 0·056/100 at 25°). 0·4842 g. required 13·8 c.c. of N/10 NaOH = 100·0% theory.

Benzidine α-naphthalenesulphonate.—An attempt was made to prepare both the basic and normal salts, but only the normal salt was obtained. This is readily prepared by adding benzidine hydrochloride to a hot solution of the acid, when an immediate precipitate is obtained, which is sparingly soluble even hot. Solubility 0·15/100 at 15°; 0·5318 g. required 17·65% c.c. N/10 NaOH = 99·6% theory m.p. above 330°.

Benzidine β-naphthalenesulphonate.—4 g. of benzidine and 5 c.c. of hydrochloric acid in 500 c.c. of water were added to 5 g. of β acid in 500 c.c. of water. An immediate grey precipitate was obtained which is difficult to recrystallise from water owing to its insolubility. It is also practically insoluble in alcohol. Solubility 0·03/100 at 15°; 0·5104 g. required 16·95 c.c. of N/10 NaOH = 99·6% (mol. wt. 600).

Tolidine α-naphthalenesulphonate.—Sufficient tolidine hydrochloride theoretically was added to a solution of α acid to form the basic salt. On cooling slightly two layers were formed, but the lower brown layer was comparatively small, and both crystallised on standing. On recrystallisation, white crystals were obtained which proved to be the normal salt in both cases, m.p. 294° (decomp.). Solubility 0·25/100 at 15°; 0·4544 g. required 14·3 c.c. of N/10 NaOH = 98·9% theory.

Tolidine β-naphthalenesulphonate.—In this case both the normal and the basic salts were obtained. *Normal salt*.—2·1 g. of tolidine and 3 c.c. of hydro

...oric acid in 100 c.c. of water were added to 6 g. free β acid in 50 c.c. of water. An immediate ...cipitate was obtained, which was recrystallised ...m a large volume of hot water. Solubility ...3/100 at 15°; 0·6742 g. required 21·4 c.c. NaOH ...% theory (mol. wt. 628). *Basic salt.*—3 g. of ...dine were added to 5 g. of free β acid in 200 c.c. water, when an immediate precipitate was ...ained. Beautiful silvery plates were obtained on ...rystallisation from water. Solubility 0·07/100 12°; 0·5120 g required 12·13 c.c. of $N/10$ NaOH ...9·6% theory (mol. wt. 420).

...Dianisidine α-naphthalenesulphonate.—Grey crys...s, m.p. 272° (decomp.). Solubility 0·28/100 at 15°: ...018 g. required 17·95 c.c. of $N/10$ NaOH ...4%. Attempts to make the basic salt only ...lded the normal salt.

...Dianisidine β-naphthalenesulphonate.—2·5 g. of ...nisidine, 5 g. of free β acid, and 200 c.c. of water ...l a little hydrochloric acid yielded glistening ...stals whilst still hot. On recrystallising, long ...ong plates were obtained, m.p. 290° (decomp.). ...ubility 0·10/100 at 15°; 0·3486 g. required ...4 c.c. of $N/10$ NaOH=98·4% theory.

...Chloroaniline α-naphthalenesulphonate.—Recrys...lises very readily from water, m.p. 237°. Solu...ity 0·49/100 at 15°: 0·3704 g. required 11·0 c.c. $N/10$ NaOH=99·9% theory.

...Chloroaniline β-naphthalenesulphonate.—Small ...ite needles, m.p. 214°. Solubility 0·35/100 at ..., 0·5002 g. required 14·9 c.c. of $N/10$ NaOH= ...0% theory.

m-Chloroaniline α-naphthalenesulphonate.—White ...tes, m.p. 176°, crystallises well from water or ...ohol. Solubility 0·29/100 at 15°; 0·6202 g. ...uired 18·55 c.c. of $N/10$ NaOH=100·3% theory.

m-Chloroaniline β-naphthalenesulphonate.—White ...stening plates, m.p. 244°, were obtained which ... sparingly soluble in hot water and alcohol. ...lubility 0·14/100 at 15°; 0·4690 g. required ...95 c.c. of $N/10$ NaOH=99·8% theory.

...p-Chloroaniline α-naphthalenesulphonate.—Colour... plates, m.p. 231°. Solubility 0·18/100 at ..., 0·6168 g. required 18·45 c.c. of $N/10$ NaOH ...4% theory.

p-Chloroaniline β-naphthalenesulphonate.—White ...flets, m.p. 252°–253°. Recrystallises readily ...m water. Solubility 0·23/100 at 15°: 0·5064 ...uired 15·05 c.c. of $N/10$ NaOH 99·7% theory.

m-Bromoaniline α-naphthalenesulphonate.—5 g. of ...cid and 3 c.c. of *m*-bromoaniline were dissolved ...3 c.c. of hydrochloric acid and 20 c.c. of hot ...ter. On cooling an emulsion was formed which ...ickly solidified. Recrystallises very readily from ...ter, m.p. 168°. Solubility 0·36/100 at 15°; 0·2914 g. ...uired 7·65 c.c. of $N/10$ NaOH=99·9% theory.

m-Bromoaniline β-naphthalenesulphonate.—White ...tes easily recrystallised from water, m.p. 237°. ...lubility 0·10/100 at 15°; 0·4878 g. required 12·8 c.c. $N/10$ NaOH=99·7% theory.

p-Bromoaniline α-naphthalenesulphonate.—Crystal...es readily from water. Colourless leaflets, m.p. ...4°. Solubility 0·35/100 at 15°; 0·5608 g. required ...8 c.c. of $N/10$ NaOH=100·3% theory.

p-Bromoaniline β-naphthalenesulphonate.—Large colourless plates, m.p. 244°. Solubility 0·10/100 at 15°; 0·4634 g. required 12·2 c.c. of $N/10$ NaOH 100·0% theory.

Phenylhydrazine α-naphthalenesulphonate.—6 g. of phenylhydrazine hydrochloride in 100 c.c. of water were mixed with 10 g. of sodium α-naphthalene sulphonate in 80 c.c. of water. On cooling large clusters of white needles, m.p. 178°, separated. Solubility 0·57/100 at 12°; 0·2966 g. required 9·05 c.c. of $N/10$ NaOH=98·4% theory.

Phenylhydrazine β-naphthalenesulphonate.—An immediate precipitate was formed on mixing the hot solutions of the acid and hydrochloride of base. White needles on recrystallisation from hot water, m.p. 217°. Solubility 0·24/100 at 10°; 0·2290 g. required 7·2 c.c. of $N/10$ NaOH=99·4% theory.

1.2.4-Dichloroaniline α-naphthalenesulphonate.—Separates as an oil which crystallises on standing. White crystals, m.p. 234°. Solubility 0·12/100 at 15°; 0·4130 g. required 11·15 c.c. of $N/10$ NaOH=99·8% theory.

1.2.4.-Dichloroaniline β-naphthalenesulphonate.—Colourless fine plates, m.p. 178°. Solubility 0·14/100 at 15°; 0·5212 g. required 14·05 c.c. of $N/10$ NaOH 99·7% theory.

o-Anisidine α-naphthalenesulphonate.—6·2 g. of lead α-naphthalenesulphonate were suspended in 40 c.c. of water and 2·5 g. of *o*-anisidine were added. Whilst hot, 20 c.c. of $N/1$ sulphuric acid were added and the lead sulphate was filtered off; the crude salt crystallised on cooling. Recrystallised readily from water in fine white needles, m.p. 208°. Solubility 0·85/100 at 10°. It did not give a sharp end-point when titrated with sodium hydroxide.

o-Anisidine β-naphthalenesulphonate.—5·5 g. of the barium salt and 2·5 g. of *o*-anisidine were suspended in 120 c.c. of water, 20 c.c. of $N/1$ sulphuric acid were added, and the barium sulphate was filtered off. White needles, m.p. 207°. Solubility 0·26/100 at 15°; 0·4880 g. required 14·8 c.c. of $N/10$ NaOH=100·4% theory.

p-Anisidine α-naphthalenesulphonate.—From the solution of the sodium salt of the acid and the hydrochloride of the base, a very bulky stringy precipitate was obtained, which when recrystallised gives an almost colloidal mass, containing much water. On drying, it contracts to a very small bulk, but holds water very tenaciously: m.p. 182°. Solubility 1·02/100 at 15°; 0·5424 g. required 16·05 of $N/10$ NaOH=97·9% theory.

p-Anisidine β-naphthalenesulphonate.—Recrystallised from water in glistening leaflets which are difficult to dry completely; m.p. 218°. Solubility 0·40/100 at 15°; 0·5314 g. required 15·9 c.c. of $N/10$ NaOH=99·1%.

o-Phenetidine α-naphthalenesulphonate.—Colourless crystals after repeated recrystallisation, m.p. 185°. Solubility 0·65/100 at 15°; 0·6800 g. required 19·7 c.c. of $N/10$ NaOH=100·0% theory.

o-Phenetidine β-naphthalenesulphonate.—Fine white needles from water or alcohol, m.p. 197°. On titration the end-point was indistinct. Solubility 0·22/100 at 10°.

p-Phenetidine α-naphthalenesulphonate.—10 g. of sodium α-naphthalenesulphonate, 5 g. of *o*-phenetidine, 5 c.c. of hydrochloric acid, and 60 c.c. of water were used, "norit" was added, and the solution filtered. On cooling, a very thick precipitate was obtained, which was recrystallised from 150 c.c. of water. Beautiful colourless large thin plates, m.p. 201°–202°. Solubility 0·19/100 at 10°; 0·3138 g. required 9·15 c.c. of $N/10$ NaOH=100·6% theory.

p-Phenetidine β-naphthalenesulphonate.—Colourless vitreous plates, m.p. 207°. Solubility 0·20/100 at 15°; 0·6292 g. required 18·2 c.c. of $N/10$ NaOH=99·8% theory.

ψ-Cumidine α-naphthalenesulphonate.—2·5 g. of *ψ*-cumidine, 5 g. of α-sodium salt, 5 c.c. of hydrochloric acid, and 30 c.c. of water gave oily globules whilst hot, and a white emulsion on cooling which quickly solidified to a white mass, m.p. 198°. Sparingly soluble in alcohol and water. Solubility 0·19/100 at 14°; 0·6196 required 17·9 c.c. of $N/10$ NaOH 99·1% theory.

ψ-Cumidine β-naphthalenesulphonate.—From 2 g. of *ψ*-cumidine, 4 g. of free β acid, 2 c.c. of hydrochloric acid, and 100 c.c. of water. A precipitate was obtained whilst still hot, which recrystallises in fine white needles from a large quantity of hot water. Very sparingly soluble in cold alcohol or cold water. Solubility 0·05/100 at 10°; m.p. 236°; 0·5576 g. required 16·15 c.c. of $N/10$ NaOH=99·3% theory.

m-Aminophenol α-naphthalenesulphonate.—8 g. of α-sodium salt and 3·3 g. of *m*-aminophenol were dissolved in 100 c.c. of water and 4 c.c. of hydrochloric acid, and allowed to stand for three days. Recrystallised from a small quantity of water, m.p. 200°. Solubility 3·08/100 at 15°; 0·6770 g. required 21·4 c.c. of $N/10$ NaOH=100·2% theory.

m-Aminophenol β-naphthalenesulphonate.—Recrystallised readily from hot water, m.p. 247°. Solubility 1·16/100 at 15°; 0·6094 g. required 19·33 c.c. of $N/10$ NaOH=100·6% theory.

p-Phenylenediamine α-naphthalenesulphonate.—Recrystallised from water in fine colourless plates, m.p. above 330°. Solubility 0·26/100 at 10°.

p-Phenylenediamine β-naphthalenesulphonate.—Recrystallised from a large quantity of boiling water, in which it is only sparingly soluble. Almost colourless large plates. Solubility 0·07/100 at 15°; 0·5472 g. required 20·95 c.c. of $N/10$ NaOH=100·2% theory.

Attempts to make the basic salt failed.

m-Phenylenediamine β-naphthalenesulphonate.—This salt was readily formed by mixing a hot alcoholic solution of the β acid and *m*-phenylenediamine, and was recrystallised from dilute alcohol. On heating it blackens at 275°. Solubility 1·27/100 at 17°; 0·5006 g. required 19·3 c.c. of $N/10$ NaOH=101·0% theory (mol. wt. 524).

m-Phenylenediamine α-naphthalenesulphonate is readily soluble in absolute alcohol, but the β-sulphonate is only sparingly soluble.

It is also interesting to note that the corresponding *m*-phenylenediamine salts are much more soluble than the *p*-phenylenediamine salts. For example, the *m*-phenylenediamine salt of the α acid is readily soluble in cold water and extremely soluble in boiling water. The *m*-phenylenediamine salt of the β acid is also readily soluble in hot water, and since the *p*-phenylenediamine salt of the β acid is only sparingly soluble in boiling water, a mixture of *m*- and *p*-phenylenediamines may be easily separated by the aid of the β acid.

m-Nitroaniline α-naphthalenesulphonate.—Recrystallises well from either water or alcohol; m.p. 261°. Solubility 0·15/100 at 15°; 0·5550 g. required 15·95 c.c. of $N/10$ NaOH=99·4%.

m-Nitroaniline β-naphthalenesulphonate.—Recrystallised from hot water gave small yellowish needles, m.p. 260°. Solubility 0·19/100 at 15°; 0·5668 g. required 16·3 c.c. of $N/10$ NaOH=99.5%.

p-Nitroaniline α-naphthalenesulphonate.—Recrystallised from absolute alcohol in yellow needles, m.p. 241° (decomp.); 0·5094 g. required 14·7 c.c. of $N/10$ NaOH=99·9% theory.

p-Nitroaniline β-naphthalenesulphonate.—Colourless needles, m.p. 247° (decomp.). Both the α- and β-naphthalenesulphonates of *p*-nitroaniline are dissociated when recrystallised from water, but they can be recrystallised readily from alcohol.

p-Nitro-o-toluidine α-naphthalenesulphonate.—When 3 g. of *p*-nitro-*o*-toluidine dissolved in alcohol were added to 5 g. of α acid in 100 c.c. of water, an immediate precipitate was formed. Fine, almost colourless needles were obtained by recrystallising from alcohol; m.p. 244° (decomp.). Solubility 0·11/100 at 15°; 0·4210 g. required 11·8 c.c. of $N/10$ NaOH=100·9% theory.

p-Nitro-o-toluidine β-naphthalenesulphonate.—Pale yellow needles on cooling, which may be recrystallised from water or alcohol, m.p. 229°–230°. Solubility 0·12/100 at 15°. 0·4160 g. required 11·37 c.c. of $N/10$ NaOH=98·4% theory.

N-Substituted aniline salts.

The salts of N-substituted anilines are difficult to prepare, inasmuch as they will not crystallise readily from an aqueous solution or alcoholic solution, and frequently two layers are formed which do not crystallise, or else the naphthalenesulphonic acid separates out. When once crystallised, however, they are usually fairly easy to recrystallise.

The following salts were prepared:—

Monomethylaniline α-naphthalenesulphonate.—White needles, m.p. 147°. Solubility, 1·65/100 at 15°: 0·6684 g. required 20·85 c.c. $N/10$ NaOH = 98·3% theory.

Monomethylaniline β-naphthalenesulphonate.—m.p. 213°.

Dimethylaniline α-naphthalenesulphonate was prepared from the lead salt of the acid and dimethylaniline hydrochloride. Long fine needles, m.p. 140°–141°. Solubility, 2·78/100 at 15°.

Diethylaniline β-naphthalenesulphonate was obtained by spontaneous evaporation of a solution of 5 g. of β acid and 5 c.c. of diethylaniline in 25 c.c. of alcohol. Reddish-brown crystals were obtained which were washed with ether and acetone, and further purified by dissolving in alcohol, precipitating by ether, and finally recrystallising from water. Fine white needles, m.p. 219°. Solubility, 0·82/100 at 15°.

Separation of mixtures of α- and β-naphthalenesulphonic acids.

The principle of the method of separating the ds is that if sufficient arylamine is added to m the β salt, that salt is precipitated, leaving the α d in solution. The salts with aniline, p-toluidine, l m-xylidine are the most suitable for this purpose, the β acid forms salts with these substances quite dily and they are easily purified. On the other nd, the p-toluidine and m-xylidine salts of α-phthalenesulphonic acid are less readily formed, l do not crystallise very readily in the crude state. erefore, if only a slight excess of amine is added to tralise the β acid, the α acid is left in the solution l may be obtained in comparatively pure state evaporation, or by the addition of a further antity of the base.

Mixtures containing 15%, 50%, and 85% of each d were made, and then separated by the above thod, the free acids being used in each case.

Separation by means of aniline salts.—(1) 6 g. of naphthalenesulphonic acid ($2H_2O$) and 6 g. of naphthalenesulphonic acid (H_2O) were dissolved in 0 c.c. of water containing a few drops of hydrochloric acid, and 2·5 g. of aniline were added. On oling and standing for one day a precipitate, p. 254°–260°, and weighing 7·21 g., was obtained, hich is equal to 89·6% theory of the β acid. On crystallisation this melted at 265°–269°, and nce was practically pure β salt. To the original other liquor, 2·5 g. of aniline were added; a precipite, weighing 5·23 g., was obtained, m.p. 183°–185°, hich was hence fairly pure α salt.

(2) 1·5 g. of β-naphthalenesulphonate (H_2O) and 5 g. of α-naphthalenesulphonic acid ($2H_2O$) were ssolved in 50 c.c. of water, and a little hydrochloric id and 1 g. of aniline was added. A precipitate on appeared which was allowed to stand for 24 ours; yield 2·18 g. Softened at 214°, and melted 250°. 1 g. of aniline should have given 3·23 g. of ixed α and β salt, and 1·5 g. of β acid should have iven 2·016 g. of aniline salt, containing 0·62 g. of niline. Thus the bulk of the β acid and a small uantity of the α acid separated when the original other liquor was evaporated. A small precipitate rst separated, and then free acid was obtained in uantity.

(3) 8·5 g. of β acid ($1H_2O$) and 1·5 g. of α acid $2H_2O$) were dissolved in 100 c.c. of water, heated to he boil, and 4 g. of aniline added, when an immediate hick precipitate was obtained—11·04 g. of m.p. 262°–267°. Recrystallised, m.p. 268°–269°. 8·5 g. f β acid ($1H_2O$) should have given 11·42 g. of aniline alt, containing 3·53 g. of aniline. Hence, almost the whole of the β acid was thus precipitated.

Separation by means of the p-toluidine salts.—(1) 6 g. f β acid and 6 g. of α acid were added to 100 c.c. of water, and 2·87 g. of p-toluidine were introduced at he boil. After standing one day 6·87 g. of the salt were obtained, m.p. 198°–203°, which is equivalent to 81·5% of β acid, though in this case it should be noted that an excess of p-toluidine was not used. On recrystallisation of the precipitated salt, pure pale yellow needles of the β salt, m.p. 221°, were obtained. When 2·87 g. of p-toluidine were added to the mother liquor a further precipitate, m.p. 169°–181°, was obtained, which consisted mainly of p-toluidine α-naphthalenesulphonate.

(2) 1·5 g. of β acid ($1H_2O$), 8·5 g. of α acid ($2H_2O$), 50 c.c. of water, and 1 g. of p-toluidine after standing for one day, gave only a slight precipitate, but on standing another 24 hours a precipitate, weighing 1·71 g., was obtained, m.p. 196°–202°. On further standing another 0·29 g. of salt was collected. The first precipitate melted at 214°–219° on recrystallisation.

The separation of the α acid from the mother liquor may be best attained by evaporation, as the p-toluidine α salt does not crystallise very well, usually separating as a stringy semi-colloidal mass holding much water.

(3) 8·5 g. of β acid (H_2O), 1·5 g. of α acid ($2H_2O$), 100 c.c. of water, and 4·25 g. of p-toluidine quickly yielded a precipitate weighing 10·62 g., m.p. 211°–213°. This, on recrystallisation, readily gave fine needles of pure p-toluidine β salt, m.p. 221°–222°.

The p-toluidine salts form highly-supersaturated solutions which only crystallise on long standing, hence the above yields are not so good as those obtained when using aniline as a separating agent.

Separation by means of the m-xylidine salts.—(1) 1·5 g. of α salt and 8·5 g. of β salt were dissolved in 100 c.c. of water, and 0·5 c.c. of hydrochloric acid and 4·8 g. of m-xylidine then added. When cold a thick precipitate, weighing 12·13 g., was filtered off (m.p. 201°–206°), which on recrystallisation, melted at 206°–209°. This was again recrystallised and two fractions were obtained, the first melting at 210°–211°, and the second at 204°–208°.

(2) 8·5 g. of α salt, 1·5 g. of β salt, 50 c.c. of water, 0·5 c.c. of hydrochloric acid, 1 g. of m-xylidine. No precipitate was obtained when cold, and on standing 24 hours only a slight precipitate, 0·91 g., m.p. 178°–185°, was obtained. This, on recrystallisation, melted at 198°–201°, and again at 209°–211°.

The aniline salt may be considered the best for separating mixtures of the two acids, but the p-toluidine and m-xylidine salts are also very effective, especially if sufficient time is allowed for the supersaturated solutions to crystallise.

The separation and identification of arylamines themselves may be effected by their salts with the naphthalenesulphonic acids, especially with the β acid. Thus m- and p-phenylenediamines may be separated as already mentioned. A mixture of mono- and di-methylaniline and β acid will first give the β salt of monomethylaniline. It is also possible, generally speaking, to separate mixtures of o- and p-substituted amines, the para salts being usually less soluble than the ortho, though this was more apparent in the case of 2.6- and 2.7-naphthalenedisulphonic acids. Generally speaking, also, these salts have well-defined melting points, and they form ready means of identification of small quantities of such bases.

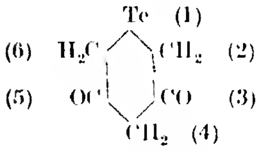
BACTERICIDAL ACTION OF TELLURIUM-β-DI-KETONES.

BY GILBERT T. MORGAN, E. ASHLEY COOPER, AND FREDERICK J. CORBY.

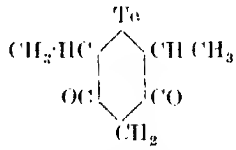
Tellurium derivatives of the aliphatic β-diketones are extremely active germicides (Morgan, Cooper, and Burtt, Biochem. J., 1923, **17**, 30; 1924, **18**, 190): for example, 2.6-dimethyl-*cyclo*-telluro-pentane-3.5-dione (II.) exerts bactericidal action in as low concentrations as 1 in 10,000,000 to 1 in 40,000,000.

The chemical structure of the simplest compound of the series, *cyclo*-telluro-pentane-3.5-dione (I), is indicated thus:—

(I.)



(II.)

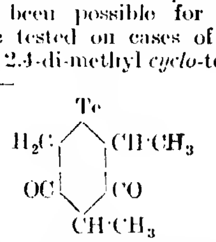


Substitution of groups is possible in any of the three methylene (CH_2) radicals, and the introduction of alkyl groups and their orientation profoundly affect the germicidal power of these new compounds. Recently a large number of additional homologues have been prepared, and the general principles correlating chemical structure and bactericidal power are indicated in this paper. (Compare Morgan, Drew and others, Trans. Chem. Soc., 1920, **117**, 1456; 1921, **119**, 610; 1922, **121**, 922; 1923, **123**, 444; 1924, **125**, 731, 759, 760, 1601.)

It was previously found (*loc. cit.* 1924) that the tellurium compounds lost their powerful germicidal action in serum, and were thus unlikely to be valuable as internal disinfectants. As, however, comparatively unimportant changes in chemical structure greatly influence germicidal power, the possibility of obtaining a compound efficacious in the blood-stream is not precluded.

The tellurium compounds are extremely active as germicides in the presence of urine, and as there is sufficient margin between their bactericidal and lethal doses, there appeared to be scope for their employment in cystitis and as urinary antiseptics. Lethal doses administered to mice induced symptoms of hæmaturia, and death soon followed (*loc. cit.* 1924).

Through the interest and help of Mr. William Gemmill it has been possible for one of these compounds to be tested on cases of cystitis. For the clinical trials, 2.4-di-methyl *cyclo*-telluro-pentane-3.5-dione (III.):—



(III.)

was selected, on account of its ease of preparation and ready solubility, and in cystitis its use has led to very beneficial results.

Mr. H. W. Archer-Hall has also kindly tested the same substance as to its possible application in the treatment of infective conditions of the eye, and has obtained highly satisfactory results in cases of conjunctivitis, blepharitis, and corneal ulceration.

The method of determining the germicidal power of the tellurium compounds generally employed consisted in exposing a definite number of organisms to the action of the compounds in lemco-peptone broth as nutrient medium for 48 hours at 37°. The organisms used were *B. coli*, *typhosus*, *paratyphosus*, *pyocyaneus*, and *Strept. hæm.* Tests have also been made with protozoa (*paramœcia*) grown in hay infusion, but the above tellurium compound acts much more powerfully against bacteria, than against protozoa, comparatively high concentrations, *e.g.* 1 in 400,000, being required to disinfect in the case of *paramœcia*.

Influence of chemical structure on bactericidal power.

Homologous series.—Members of three series as far as the butyl derivatives have been prepared, and their bactericidal power has been determined. The homologous series may be regarded as formed by the introduction of alkyl groups in the molecule of *cyclo*-telluro-pentane-3.5-dione (I) by replacement of hydrogen in one or more of the three methylene groups (2, 4, 6).

It was found that bactericidal power at first increased as the homologous series was ascended, until with the third member a maximum efficacy was attained, and the higher members showed diminishing germicidal action. Chemically, this means that the introduction of two methyl groups produces the zenith in bactericidal power, and further substitution is unfavourable. The results obtained with one typical homologous series are tabulated at the end of the paper.

Isomerism.—As substitution of alkyl groups is practicable in any of the three positions (2, 4, 6), it is evident that there are many possibilities of isomerism.

An examination of the germicidal power of a large number of isomeric compounds has led to the important conclusion that the maximum efficacy is associated with the presence of one methyl group in each of the 2-6 or ortho positions to the tellurium, 2.6-dimethyl-*cyclo*-telluro-pentane-3.5-dione (II) therefore, being the most active of the series and bactericidal in concentrations varying from 1 in 10,000,000 to 1 in 40,000,000 to several coliform organisms.

Dissymmetric substitution in one only of the 2—6 positions or substitution in the 4 or para-position is in general much less favourable, and leads to compounds of lower bactericidal power. Thus, the substance 2.4-dimethyl-*cyclo*-telluropentane-3.5-dione is less active than the above isomeride, being bactericidal in concentrations varying from 1 in 5,000,000 to 1 in 20,000,000. It was employed in the clinical trials, however, as it is more soluble and easily prepared.

Other tellurium derivatives have also been recently prepared, in which the difference in chemical constitution does not depend on the position of the alkyl

groups in the heterocyclic ring, but merely on the structure of the alkyl group itself, for instance as between propyl, $CH_2.CH_2.CH_3$, and *iso*propyl, $CH(CH_3)_2$.

This small local difference was found to affect germicidal power in a somewhat important manner, the *iso*propyl compounds being from two to four times as active as their *n*-propyl isomerides. The *n*-butyl derivative, $-CH_2(CH_2)_2CH_3$, however, was more active than the isomeric *iso*butyl, $-CH_2.CH(CH_3)_2$ compound. The results are of importance insomuch as they indicate that the bactericidal power of the *cyclo*-telluro-pentane-3.5-diones is readily influenced by quite small changes in chemical structure, and there is thus a possibility of obtaining a suitable compound, retaining its germicidal action *in vivo*.

The introduction of an aromatic group, *e.g.*, benzyl, resulted in compounds possessing bactericidal power of very much the same order as that of the aliphatic tellurium derivatives.

It is remarkable that the parent aliphatic β-diketones themselves are only feeble germicides (the bactericidal concentrations varying from 1 in 100 to 1 in 400), showing that the tellurium-carbon heterocyclic ring plays a very important part in the manifestation of bactericidal action. This is confirmed by the observations that the selenium, copper, iron, and cobalt derivatives possess only slight germicidal powers. It is also essential that the tellurium should exist in the unsaturated state, as the oxides and basic derivatives in which the tellurium is quadrivalent are very weak disinfectants.

Germicidal action in serum.

The serum (ox) was first heated at 56° to destroy its bactericidal properties and ensure sterility. The organisms were incubated in the serum, containing varying concentrations of the tellurium compounds, for 24 hours at 37°. Sub-cultures were then made into broth, and the minimum bactericidal concentration could thus be determined for each substance.

It was found that concentrations, ranging from 1 in 50,000 to 1 in 200,000, were required for complete disinfection in serum, indicating a very serious collapse in germicidal power, but notwithstanding this remarkable diminution in efficacy, changes in chemical structure were found to influence bactericidal power in serum in very much the same way as in peptone-broth media.

Serum still reduced the bactericidal power of the tellurium compounds, even after dialysis, showing that the incompatible substance is colloidal in nature. The interfering substance, however, does not appear to be a protein, as serum-proteins, gelatin, egg-albumin, caseinogen, and proteoses had no effect on germicidal power. Lecithin, carbamide, creatinine, and ammonium carbonate were also without effect, but glycine had the noteworthy property of increasing germicidal power.

Influence of the time-factor on germicidal power.

So far the bactericidal action of the tellurium compounds has been studied over periods of 24 or 48 hours. We have found, however, that these germicides are capable of acting much more rapidly than was originally supposed, as they can exert an appreciable bactericidal action in 1 hour, but their maximum efficacy is not attained until after a period of about 4 hours.

This confirms the view already expressed that the foregoing tellurium derivatives are true germicides, and not merely growth-inhibitors.

Results illustrating the germicidal power of the members of a homologous series of tellurium compounds.

(B. coli communis)

Substance	Bactericidal concentrations
cyclo-Telluro-pentane-3.5-dione	1 in 500,000
2-Methyl	1 in 3,000,000
2.4-Dimethyl	1 in 20,000,000
2-Methyl-4-ethyl	1 in 13,000,000
2-Methyl-4-propyl	1 in 8,000,000
2-Methyl-4-butyl	1 in 7,500,000

Summary

1. The *cyclo*-telluropentane-3.5-diones are very powerful germicides, exerting a marked bactericidal action in certain cases in as low concentrations as 1 in 1,000,000 to 1 in 20,000,000. Their maximum effect is observed after about 4 hours' contact with the organisms.

2. The bactericidal power of these substances is influenced by the number and distribution of alkyl groups in the molecule, the maximum activity being associated with the presence of two methyl groups substituted in the 2-6 or ortho-positions to the tellurium atom in the heterocyclic ring.

3. Bactericidal power may also be influenced by even smaller isomeric differences, the *iso*propyl and *iso*butyl derivatives, for example, differing in germicidal power from the corresponding normal isomerides.

4. The toxic effect of the *cyclo*-telluro-pentane-3.5-diones on protozoa is much less marked than their bactericidal action.

5. Aromatic derivatives of these substances offer no special advantage as disinfectants over the aliphatic compounds.

6. The parent aliphatic diketones are very feeble germicides, indicating that the outstanding bactericidal power of their tellurium derivatives is associated with the tellurium-carbon heterocyclic ring. The presence of unsaturated tellurium is also essential for high germicidal power, as the activity of the compounds is greatly diminished when the metalloid is raised to the quadrivalent condition.

7. The tellurium compounds lose their outstanding bactericidal action in the presence of serum. The incompatible constituent is colloidal, but does not appear to be a protein. They retain their germicidal efficacy, however, to a large extent in the presence of urine.

8. Notwithstanding the poisonous nature of the tellurium-β-diketones and their property of inducing haematuria, there is sufficient margin between their lethal and bactericidal concentrations, and 2.4-dimethyl-*cyclo*-telluro-pentane-3.5-dione, which is readily prepared and soluble in water, has been used with success in the treatment of cystitis, and eye infections.

The authors desire to express their best thanks and appreciation to Mr. William Gemmill and Mr. H. W. Archer-Hall for their interest and help in undertaking the clinical trials, to the Government Grant Committee of the Royal Society and to the Advisory Council of the Department of Scientific and Industrial Research for grants which have helped to defray the expenses of this investigation.

MOULDS ON FROZEN MEATS.

BY F. T. BROOKS.

In a paper by A. M. Wright (J., 1923, 488 T), it is stated that "black spot" of cold-store meat is due not only to *Cladosporium herbarum*, but also to *Mucor mucedo* and *Penicillium glaucum*. On the other hand, Brooks and Kidd and Brooks and Hansford (Special Reports 6 and 17, Food Investigation Board), found in their researches on mould contaminations of meat that "black spot" was exclusively due to the fungus *Cladosporium herbarum*. In view of this discrepancy, two of Wright's experiments of which details are given by him, have been repeated in the Low Temperature Research Station at Cambridge, the results of which invalidate Wright's view that "black spot" of meat may be caused by other fungi than *Cladosporium herbarum*. Thus mutton was inoculated with the spores of *Mucor mucedo*, and kept at a temperature of —1° C. until growth was well established, after which the meat was kept at a temperature of —11° for four and a-half months. Upon examination after this period there was found no trace of "black spot," but only the typical growth of *Mucor*. Similarly mutton inoculated with a species of *Penicillium*, and kept at 4° until the fungus was well developed, showed no trace of "black spot" after being kept for four and a-half months at —11°; again, only the typical growth of *Penicillium* was apparent.

If Wright's contention that "black spot" may be due also to *Mucor* and *Penicillium* be true, one wonders what is the cause of the black colour of such spots, for the hyphæ of both *Mucor* and *Penicillium* are colourless. Brooks and Kidd have shown that in all the "black spots" examined by them the colour was caused by the dark hyphæ of *Cladosporium herbarum*.

Wright states that *Mucor mucedo*, a *Rhizopus* and *Penicillium glaucum* were often isolated by him from "black spots." This is not surprising, as these moulds are often superimposed upon meat contaminated by *Cladosporium herbarum*. Under such conditions special precautions must be taken to isolate *Cladosporium herbarum*, as this fungus grows slightly deeper in the tissues than the other moulds.

NITRATION OF STEREOISOMERIC AROMATIC DIAMINES.

BY GILBERT T. MORGAN AND WILFRED JOHN HICKINBOTTOM.

It has previously been demonstrated that $\beta\gamma$-di-p-tolyl-aminobutane ($\beta\gamma$-butylene-di-p-toluidine) exists in four stereoisomeric forms (J. Chem. Soc., 1923, **123**, 97), and the present communication deals with the nitration of the externally and internally compensated modifications. The object of the investigation was to ascertain whether the different spatial arrangement of the aromatic radicals of these diamines would be revealed by differences in the behaviour of the bases towards substituting agents.

The experimental results recorded below show that the *dl*-diamine and the *meso*-base (II.) behave in a precisely similar manner. Any slight variations in ease of nitration or in yields are to be attributed merely to differences in the solubility of the products under the conditions of experiment.

Two methods of nitration were adopted :—

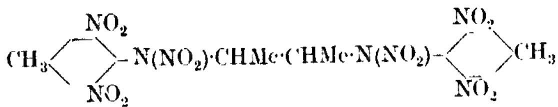
(1) Nitration in acetic acid or acetic anhydride.

(2) Nitration of the sulphate of the base with concentrated nitric and sulphuric acids.

The following diagram, which applies both to *dl*-$\beta\gamma$-di-p-tolylaminobutane (the conglomerate of the *d*- and *l*- forms) and to *meso*-$\beta\gamma$-di-p-tolylaminobutane, illustrates the course taken by each of the methods of nitration.

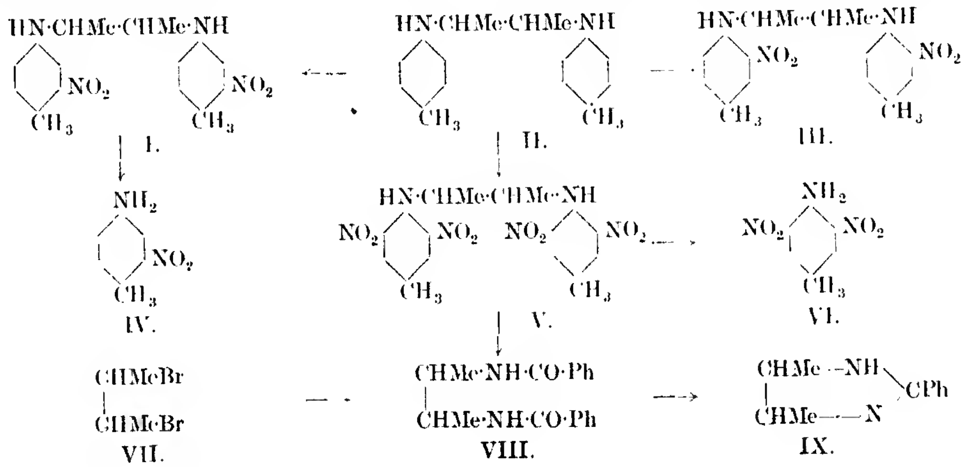
In the absence of any other strong mineral acid, the action of nitric acid on the two stereoisomerides (II.) leads to *dl*- and *meso*-$\beta\gamma$-*3.3'-dinitrodi*-p-*tolylaminobutane* (III.). By more drastic treatment with stronger nitric acid the two stereoisomeric bases yield respectively *dl*- and *meso*-$\beta\gamma$-3.3'.5.5'-*tetranitrodi*p-*tolylaminobutane* (V.).

In this mode of nitration the positions taken up by the nitro groups show that the alkylenediamino group is the orienting agent. This effect is probably due to the circumstance that the first action of the nitric acid is to form a nitrate which becomes dehydrated to a nitramine, the latter compound then undergoing isomeric change by migration of the nitro group into the ortho position in the ring. When both ortho positions are already occupied by nitro groups, this isomeric change is no longer possible, and the nitramine can be isolated. This result was achieved by nitrating the *dl*-diamine with excess of nitric acid in presence of acetic anhydride, when *dl*-$\beta\gamma$-*butylene*-3.3'.5.5'-*tetranitrodi*-p-*tolyldinitramine* (X.) was produced.



Nitration takes a different course, however, when it is effected on the sulphate of the diamine in concentrated sulphuric acid. Here the reactivity of the aminic nitrogen is destroyed by salt formation, and the methyl group becomes the prepotent orienting factor. The stereoisomerides (II.) give rise to *dl*- and *meso*-$\beta\gamma$-*2.2'-dinitrodi*-p-*tolylaminobutane* (I.).

The orientation of the nitro groups in the foregoing nitration products of the di-p-tolylaminobutanes was determined by acid hydrolysis, using moderately concentrated sulphuric acid, when the two dinitrodiamines (I.) obtained by the sulphate method yielded 2-nitro-p-toluidine (IV.). The tetranitrodiamines (V.) produced by nitration in acetic acid when hydrolysed in this way furnished 3.5-dinitro-p-toluidine (VI.). The constitution of the other two dinitrodiamines (III.) is reached by exclu-



sion and confirmed by the fact that further nitration leads to the corresponding 3.5.3′.5′-tetranitrodiamines (V.)

Alkaline hydrolysis in alcohol of these tetranitrodiamines (V.) leads to fission occurring between the aminic nitrogens and the ring. 3.5-Dinitro-*p*-cresol remains in the alkali whilst the stereoisomeric *βγ*-diaminobutanes are obtained by distillation. These are identical with the diamines obtained by the action of ammonia on *sym*-butylene dibromide (VII.), and are characterised by their *dibenzoyl* derivatives (VIII.) and by the conversion of these compounds into *iminazoles* (IX.)

dl-βγ-3.3′.5.5′-Tetranitrodi-p-tolylaminobutane (V.), m.p. 230°, orange-yellow needles from glacial acetic acid, sparingly soluble in acetone and ether; it contained 18·90% N; $C_{18}H_{20}O_8N_6$ requires N=18·75%. Addition of 50% potassium hydroxide to an acetone suspension of the nitroamine produced a reddish-purple coloration; the acetone layer gradually changed colour through light red to orange, whilst the lower layer, initially colourless, assumed a dark red tint. *Preparation.*—A solution of 4 grams of *dl-βγ*-di-*p*-tolylaminobutane in 25 c.c. of glacial acetic acid was added during 30 minutes with stirring to 60 c.c. of colourless fuming nitric acid (*d.* 1·5) and 60 c.c. of glacial acetic acid, maintained below −10° throughout the nitration, which was completed by allowing the mixture slowly to attain the room temperature for 2½ hours. A crystalline deposit separated, and the product, which was isolated by pouring on to ice, was washed with acetone and crystallised from glacial acetic acid (yield 67–75%).

dl-βγ-Butylenetetranitrodi-p-tolyldinitramine (X.), pale yellow tablets, almost white crystalline powder from fuming nitric acid, decomposed at 178°–180° with evolution of oxides of nitrogen; sparingly soluble in alcohol or ether, dissolving more readily in acetone. N=20·87%; $C_{18}H_{18}O_{12}N_8$ requires N=20·82%.

Preparation.—*dl-βγ*-Di-*p*-tolylaminobutane (3 g.) in 7 g. of glacial acetic acid was added to 50 c.c. of fuming nitric acid (*d.* 1·5) and acetic anhydride in equal volumes. After five hours the precipitate on ice was crystallised from glacial acetic acid.

dl-βγ-3.3′-Dinitrodi-p-tolylaminobutane (III.), brownish-red needles, m.p. 200°; not readily soluble in cold acetone or alcohol, more readily in chloroform. N=15·83%; $C_{18}H_{22}O_4N_4$ requires N=15·64%.

Preparation.—The externally compensated amine (1 g.) dissolved in 10 c.c. of glacial acetic acid was added slowly to 10 c.c. of nitric acid (*d.* 1·42) and 25 c.c. of glacial acetic acid at 0°. After four hours the solution was poured on to ice, and the precipitate crystallised from glacial acetic acid.

dl- or r-βγ-2.2′-Dinitrodi-p-tolylaminobutane (I.), m.p. 132°, orange needles from glacial acetic acid; orange hemispherical aggregates of small needles from a mixture of carbon tetrachloride and chloroform. Sparingly soluble in alcohol or carbon tetrachloride, more so in chloroform or acetone. N=15·84%; $C_{18}H_{22}O_4N_4$ requires N=15·64%.

Preparation.—To *dl-βγ*-di-*p*-tolylaminobutane (2·55 g.) dissolved in 110 g. of sulphuric acid (*d.* 1·84) at 0° was added a solution of 1 mol. of nitric acid (*d*=1·42) in 1 vol. of sulphuric acid. After several hours the solution diluted with crushed ice was partially neutralised with aqueous ammonia. The precipitated nitroamine, which crystallised from glacial acetic acid, yielded colourless salts: *hydrochloride*, *hydrobromide*, and *sulphate*, but these were readily dissociated by water. With formaldehyde it furnished a lemon-yellow crystalline condensation product.

meso-βγ-3.3′.5.5′-Tetranitrodi-p-tolylaminobutane (V.), m.p. 212°; minute orange plates or tablets from benzene, giving the same colour reaction as its externally compensated isomeride with sodium hydroxide and acetone. N=19·1%; $C_{18}H_{20}O_8N_6$ requires N=18·75%. *Preparation.*—One gram of *meso*-amine in 5 c.c. of glacial acetic acid was added slowly to 5 c.c. of glacial acetic acid and 15 c.c. of colourless fuming nitric acid (*d* 1·5) cooled to −15°. After keeping at −10° for fifteen minutes the mixture was poured on to ice and the bulky yellow precipitate extracted with small quantities of warm acetone. The residue consisted of practically pure *meso-βγ-3.3′.5.5′-tetranitrodi-p-tolylaminobutane.*

The weight of tetranitro compound varied in different preparations, but with efficient cooling a 40–50% nitration was effected. The yield was greatly reduced if during nitration the temperature reached 0°, and the product then contained a considerable proportion of a substance readily soluble in acetone, which separated from acetic acid in bright yellow slender needles, melting and decomposing at 163°–164°. Its reactions indicated that it was probably the tetranitrodinitrosamine of ditolylaminobutane.

meso-βγ-3.3′-Dinitrodi-p-tolylaminobutane (III.), m.p. 195°; scarlet platelets from acetone, sparingly soluble in alcohol or glacial acetic acid. Neither this substance nor the corresponding *dl*-compound gave any colour with sodium hydroxide and acetone. N=15·86%; $C_{18}H_{22}O_4N_4$ requires N=15·64%. *Preparation.*—By nitrating the *meso*-amine under the same conditions as those described for the preparation of externally compensated 3.3′.5.5′-tetranitrodi-*p*-tolylaminobutane. It also resulted from the nitration of the *meso*-base with a more dilute solution of nitric acid in glacial acetic acid.

meso-βγ-2.2′-Dinitrodi-p-tolylaminobutane (I.), m.p. 186°; from ethyl acetate in nodular masses, from acetic acid in yellowish-orange needles; sparingly soluble in benzene, more so in xylene. N=15·74%; $C_{18}H_{22}O_4N_4$ requires N=15·64%. *Preparation.*—By nitration of *meso* di-*p*-tolylaminobutane in a large excess of sulphuric acid (see nitration of *dl*-amine in presence of sulphuric acid).

The action of acids on meso- *and* dl-*βγ-2.2′-dinitrodi-p-tolylaminobutane.*

meso-2.2′-Dinitrodi-*p*-tolylaminobutane when heated with concentrated hydrochloric or hydrobromic acid for 9—10 hours in sealed tubes at about 170°, gave small yields of 2-nitro-*p*-toluidine together with crystalline halogenated products. The corresponding externally compensated nitro compound behaved in a similar manner.

A more satisfactory degradation of these isomerides into 2-nitro-*p*-toluidine was effected by means of moderately concentrated sulphuric acid. To the dinitro compound (1·2 g.) suspended in 10 c.c. of water, 10 c.c. of concentrated sulphuric acid were added; the white precipitate of the sulphate dissolved on heating to a solution which became violet and finally almost black. When the suspended solid had dissolved, 60 c.c. of water were added and the heating was continued for about 15 minutes. The solution was then diluted further, made alkaline by dilute ammonia, and filtered from a flocculent impurity. The filtrate on extraction with benzene and ether furnished 2-nitro-*p*-toluidine mixed with a small quantity of tarry matter. By crystallisation from petroleum (b.p. 80°–100°), 2-nitro-*p*-toluidine was obtained in flattened yellow needles, m.p. 76°—77·5°.

The nitro-*p*-toluidines from externally compensated 2 2′-dinitrodi-*p*-tolylaminobutane and the analogous *meso*-isomeride were identical and were characterised as 2-nitro-*p*-toluidine.

The action of sulphuric acid on meso- *and* dl-$\beta\gamma$-*3 3′.5.5′-tetranitrodi-*p*-tolylaminobutane.*

The tetranitro compound (0·7 g.) was moistened with water (about 1 c.c.) and 10 c.c. of concentrated sulphuric acid were added. A reddish solution resulted which, on further heating, darkened in colour. During the heating water was gradually added. When yellowish vapours appeared the solution was cooled, diluted largely, and the precipitated nitro compound collected and crystallised from benzene, alcohol, or carbon disulphide. The crude product from the externally compensated tetranitro compound melted at 165°–166° after softening slightly from 155°. Successive crystallisation from alcohol and carbon disulphide raised the melting point to 167°–168°.

The crude product from *meso*-$\beta\gamma$-3.3′.5.5′-tetranitrodi-*p*-tolylaminobutane melted at 165°–167° after washing with alcohol and crystallisation from benzene, it separated in yellow flattened needles.

There was no depression of melting point when the products from the *meso*- and externally compensated nitro compounds were mixed together, or when admixed with a specimen of 3.5-dinitro-*p*-toluidine.

*The action of sodium hydroxide on $\beta\gamma$-3 3′.5.5′-tetranitro-di-*p*-tolylaminobutane.*

The externally-compensated tetranitro compound (2 g.) was heated with 4 g. of sodium hydroxide in 75 c.c. of aqueous alcohol until the solid had dissolved. The volatile products of the decomposition were removed by distillation in steam, the distillate was acidified with hydrochloric acid and evaporated to dryness. The crude hydrochloride, after redissolving in water and filtering to remove the small amount of insoluble matter, was converted into the benzoyl compound. It was found advisable after rendering alkaline to remove traces of ammonia by subjecting the solution to diminished pressure before adding benzoyl chloride.

The benzoyl compound melted at 220°—224° after washing with ether, and did not depress the melting point of *dibenzoyldiaminobutane* of similar purity. It was characterised by conversion into the *iminazole* by heating in a current of hydrogen chloride (see p. 310 T). The *picrate* of the cyclic base melted at 175°—178° after commencing to soften at 165°. No depression of the melting point was observed when it was mixed with a specimen of *2-phenyl-4 5-dimethyliminazole* of similar purity (p. 310 T).

The decomposition of the *meso*-tetranitro compound was effected in a manner similar to that used for the externally compensated isomeride. The amount of material available was small, but the resulting diaminobutane was identified as its benzoyl derivative.

The action of ammonia on $\beta\gamma$-dibromobutane.

A mixture of 700 c.c. of alcoholic ammonia saturated at 0° and $\beta\gamma$-dibromobutane (93 g.) was left for a week at the ordinary temperature, then resaturated with dry ammonia and heated at 110°—125° in a rotating autoclave (Morgan and Vining, Chem. Soc. Trans., 1920, **117**, 780) for ten hours. The reaction product was then cautiously neutralised with hydrochloric acid and the excess of solvent and volatile bromo compounds were removed by distillation (A). A brownish residue remained, which, after evaporating to dryness twice with hydrochloric acid, was extracted with absolute alcohol to eliminate the bulk of ammonium salts. The alcoholic extract was evaporated and the resulting dark viscid mass of hydrochlorides treated at 0° with concentrated aqueous sodium hydroxide. A dark oil (B) having a strong basic odour separated and was dried over solid potassium hydroxide. From the strongly alkaline aqueous layer remaining after the removal of (B) further amounts of amines were obtained by extraction with ether or by steam distillation.

Isolation of bromobutylene (*Δ^{β}-bromobutene*).—Dilution of the distillate (A) with a large volume of water precipitated a heavy, colourless oil which after washing and drying distilled chiefly between 88° and 93°. On re-fractionation the bulk of the liquid was collected between 87·5° and 92° as a dense colourless liquid, which reduces a cold neutral aqueous solution of potassium permanganate. Its properties agree with those recorded for β-bromobutylene (Wislicenus and Schmidt, Annalen, 1900, **313**, 215). In two experiments the yield amounted to 44 g. from 187 g. of dibromobutane.

Isolation of $\beta\gamma$-diaminobutane.—The dark basic oil (B) left over solid potassium hydroxide for two weeks was systematically fractionated. The molecular weight of each fraction, determined by titration against standard acid assuming that only dibasic amines are present, is given in the following table:—

Fraction collected at.	Mol. wt.	Nitrogen. %
—120°	133	—
120°—130°	118 5	—
130°—135°	107	26 15
135°—145°	112	25 5
145°—150°	125	—
150°—160°	138	20·13

$C_4H_{12}N_2.H_2O$ requires N=26·39%, mol. wt.=106·1. The fractions 120°–150° all had a characteristic odour, fumed in moist air or in presence of acid vapour, and gradually became solid when exposed to

the atmosphere in an open dish. A drop when rubbed between the fingers had a slight "soapy" feel.

An examination of the fraction 130°—135°, which appeared to consist of approximately pure diaminobutane hydrate, showed that it was probably a mixture of stereoisomerides. Benzoylation gave a product melting at 195—205° after washing with ether. After several crystallisations it melted at 236°—238°. Similar results were obtained by crystallisation of the benzoyl derivatives of other fractions, and by benzoylation of the purified oxalate; m.p. 235° with decomposition. Angeli (Ber., 1890, **23**, 1358) gives m.p. 237·5—238° with decomposition.

βγ-Dibenzoylaminobutane, prismatic needles from alcohol. N = 9·45%; $C_{18}H_{20}O_2N_2$ requires N = 9·45%.

βγ-Di-p-toluenesulphonylaminobutane, flattened needles or plates from alcohol, the highest melting point being 178°—179°. A number of fractions were obtained melting between 140° and 170°. N = 7·39%; $C_{18}H_{24}O_4N_2S_2$ requires N = 7·07%.

βγ-Diaminobutane picrate, bright yellow crystalline powder decomposing at 250°—252° after darkening from about 220°; purified by repeated extraction with water. N = 20·62%; $C_4H_{12}N_2,2C_6H_3O_7N_3$ requires N = 20·51%.

2-Phenyl-4.5-dimethyliminazole (IX.).—Dry hydrogen chloride was led over fused dibenzolyaminobutane of highest melting point until no more benzoic acid sublimed away; the residue then contained the hydrochloride of *2-phenyl-4.5-dimethyliminazole*. The base itself crystallised from a mixture of benzene and light petroleum in needles, m.p. 101°—103°. Its *picrate* formed small, light yellow tufts from alcohol, m.p. 190°. N = 17·45%; $C_{11}H_{14}N_2,C_6H_3O_7N_3$ requires N = 17·37%.

From dibenzoylaminobutane of lower melting point, cyclic bases were obtained having the properties of iminazoles. They were either semi-solid or oily and yielded *picrates* of lower melting points which could not readily be separated by crystallisation.

The authors desire to express their thanks to Captain Desborough of the R.N. Cordite Factory for a supply of *n*-butyl alcohol and to the Advisory Council of the Department of Scientific and Industrial Research for a grant which has partly defrayed the expense of this investigation.

AROMATIC HYDROCARBONS IN BURMAH PETROLEUMS.

BY H. M. MULANY, M.SC., AND E. R. WATSON, D.SC.

The petroleums of Assam and Burmah are known to contain high percentages of aromatic hydrocarbons, and a process was recently worked out for the manufacture of trinitrotoluene from Assam and Burmah petrols (Indian Patent 6802 of 1921; see also Indian Industries and Power, March, 1923).

Our present research is an extension of the work then done, and was undertaken in order to identify the more important aromatic hydrocarbons in the petrol and kerosene fractions of Burmah oil.

The kerosene was fractionated from a flask using an eight-pear Young's column, and nineteen fractions were collected, the first being below 100°, the second up to 130°, and every successive one at an interval of 10°. The residue was a dark liquid. Several distillations were carried out to collect a sufficiently large quantity of each fraction.

When the specific gravity of each fraction was determined and plotted against its boiling point an almost smooth straight-line graph was obtained; it had been hoped to obtain well marked maxima of points of inflexion where the fractions would contain the highest percentage of aromatic compounds.

The bulkier fractions were then taken for examination. The percentage of aromatic hydrocarbons was determined by Thole's method (J., 1919, 39T), and the first few fractions were mononitrated, but this method was soon abandoned, as some polynitro-compounds which were always formed simultaneously gave trouble in purification by distillation. The method then adopted was to form the polynitro compound or the barium salt of the sulphonic acid so as to obtain a crystallisable product.

Later it was found better to isolate the aromatic hydrocarbons by Armstrong's method (Chem. Soc. Trans., 1884, **45**, 148). The total aromatic hydrocarbons recovered were then fractionally distilled, and the larger fractions were polynitrated, sulphonated, and oxidised. In one case a picrate was obtained. The chief aromatic compounds thus identified in the kerosene oil were *m*-xylene, *p*-cymene, and *β*-isoamylnaphthalene.

The petrol was fractionally divided into three parts, the first two being distilled at temperatures calculated to separate the benzene and toluene. The second part had been already examined during the investigation on the manufacture of TNT. The first part showed benzene and also quite a large quantity of toluene. The third part contained not only *o*- and *p*-xylenes as expected, but also some mesitylene and perhaps higher hydrocarbons.

The kerosene.

"B.O.C. Water White" kerosene was chosen for our experiments. Its fractionation has already been described. The specific gravity determinations and mononitration of some of the fractions having proved useless, attention was directed on obtaining crystallisable products by polynitration or by sulphonation.

Fraction No. 5 (150°—160°).—This was the first large fraction in the series.

1. *Polynitration.*—50 c.c. of the fraction, containing roughly 22·5% of aromatic compounds, were mononitrated by adding a cold mixture of 8·05 c.c. of sulphuric acid (*d* 1·84) and 6·35 c.c. of nitric acid (*d* 1·4), keeping the temperature below 50°. The acid was then run off and the mononitro compound

extracted from the aliphatic hydrocarbon layer by 36·2 c.c. of cold concentrated sulphuric acid in several successive fractions. Trinitration or polynitration was then carried out by cautiously adding 11·35 c.c. of nitric acid (*d* 1·5) to the sulphuric acid extract obtained above, keeping the temperature below 50°. The temperature was then raised to 70° in half an hour and from 70° to 120° in 3½ hours. The mixture was kept at 120° for one hour, and when cooled was poured into an excess of cold water and the solid crude product filtered, washed at the pump with cold water, dried, washed with ether, and crystallised from alcohol. Recrystallisation yielded mainly yellowish-white needle-shaped crystals, m.p. 181°—182°, apparently of trinitro-*m*-xylene (m.p. 182°). A small quantity, remaining insoluble in hot alcohol, gave crystals melting at 185° out of glacial acetic acid.

2. *Sulphonation* was effected with three volumes of 98% sulphuric acid in the cold. The barium salt was prepared and crystallised. An end crop gave on analysis Ba 25·72, C 40·69, H 4·62%; the barium salt of the cumenemonosulphonic acid $(C_9H_{11}SO_3)_2Ba$ contains Ba 25·65, C 40·33, H 4·11%. Also, the melting point of 3.5.6- trinitrocumene is 185°, which agrees with the melting point of the smaller crop of polynitro compound crystallised from acetic acid.

Recovery of the aromatic hydrocarbons.—Armstrong's method (*loc. cit.*) was found to be the most suitable for this purpose. 1300 c.c. of kerosene thus treated yielded 120 c.c. of aromatic hydrocarbons, which were then fractionally distilled, using a column of 8 pears and an air condenser. The quantities of fractions obtained were as tabulated below:—

No of fraction.	Range of temperature.	Weight of fraction. g.	Possible hydrocarbons.
1	44°—50°	1·0	
2	76°—80°	1·2	benzene.
3	90°—105°	0·4	
4	120°—130°	2·3	
5	130°—140°	3·5	*m*- and *p*-xylenes
6	140°—150°	12·4	*o*-xylene, much between 141° and 144°
7	150°—160°	5·4	much between 152° and 154°; cumene.
8	160°—170°	2·4	mesitylene, pseudocumene
9	170°—180°	9·2	hemimellithene, *m*-cymene, butylbenzene.
The flask had to be changed during this range.			
10	180°—190°	9·0	*o*- and *p*-cymenes, butylbenzene. durene.
11	190°—200°	0·6	
12	200°—210°	1·4	prehnitene.
13	210°—220°	4·1	naphthalene.
14	220°—230°	2·3	
15	230°—240°	3·7	pentamethylbenzene
16	240°—250°	8·1	methylnaphthalene.
17	250°—260°	3·7	ethylnaphthalene.

Residue, 12·6 g.

Fractions 6, 9, 10 and 16 are thus the most important. It is also probable that there are only three chief substances represented by fraction 6, fractions 9 and 10, and fraction 16. Our efforts were therefore concentrated on these fractions. In a later experiment to recover a further quantity of aromatic hydrocarbons the conditions were slightly changed to avoid the use of a large volume of acid, by heating the kerosene with only an equal volume of 100% sulphuric acid on a water bath, under a reflux condenser, for three hours, with occasional shaking. Much sulphur dioxide was evolved this time and the yield of aromatic hydrocarbons was smaller; the three maxima were also not so marked in this case.

I. *Aromatic fraction* 6 (b.p. 140°–150°) was polynitrated as described above. 8 g. of the hydrocarbon thus yielded 7 g. of a crude whitish-yellow solid which, after washing with ether and then with cold alcohol, and crystallising from hot absolute alcohol yielded needle-shaped crystals of m.p. 183°–185° (mainly 185°) containing 17·46% of nitrogen. 2.4.6Trinitro-*m*-xylene melts at 182° and contains 17·42% N, whilst trinitrocumene (m.p. 185°) contains only 16·47%. The boiling point of the fraction is 140°–150°, but most of it distilled between 141° and 144°. The boiling point of *m*-xylene is 139°. It appears therefore that this fraction corresponds with the aromatic compounds in the fifth fraction of kerosene already examined.

II. *Aromatic fractions* 9 *and* 10 *mixed* (b.p. 170°—190°). It was believed that these fractions represented mainly one prominent hydrocarbon, b.p. approx. 180°. The mixed fraction was examined as follows:—

Trinitration was carried out as previously, the solid crude product was washed with light petroleum ether and then with cold alcohol and purified by repeated crystallisation from hot alcohol. The product had m.p. 176°–178°, and contained 16·50% N. $C_{10}H_{11}(NO_2)_3$ requires 15·5% N, and $C_9H_9(NO_2)_3$ 16·64%; but compounds of the latter formula are mostly ruled out by their melting point or the boiling points of their parent hydrocarbons. Trinitro-*p*-cymene melts at 178°–180°, whilst *p*-cymene itself has b.p. 175°.

Sulphonation was effected by heating with an equal volume of 100% H_2SO_4 at 100° for 3 hrs. The barium salt was obtained in four crops of feathery, needle-shaped crystals containing $Ba(SO_3)_2$, 52·85%, C 42·12%, H 5·21% $(C_{10}H_{13}SO_3)_2Ba$ requires $Ba(SO_3)_2$ 53·19, C 42·20, H 4·61%.

Oxidation with aqueous permanganate.—Oxidation by Semmler's method ("Die aetherischen Oele," vol. 5, 22) yielded a substance of m.p. above 300°, and showing a tendency to sublime and flash back during combustion; it gave a methyl ester of m.p. 139°—140° by Mulliken's test for the phthalic acids: the corresponding ester of *p*-phthalic acid melts at 140°. Elementary analysis showed C 57·79% H 4·67%; phthalic acid requires C 57·83% H 3·61%.

The evidence given by all these results is strongly in favour of the presence of *p*-cymene.

Aromatic fraction 16 (*b.p.* 240—250°).—The boiling point of this third largest fraction would suggest the presence of a homologue of anthracene or naphthalene. But the former class is ruled out, being all solids; the latter type of compounds are possible, being mostly liquids. This fraction was rather troublesome to handle. Neither its polynitro compound nor its barium sulphonate could be obtained in a crystalline condition, and a quantity was prepared directly from the corres-

ponding fraction (*i.e.*, the fourteenth) of the kerosene by Armstrong's method.

The barium sulphonate was prepared directly from the corresponding kerosene fraction by heating on a water-bath with 1/10 vol. of 100% H_2SO_4 for three hours. The salt was obtained in four crops, all of which were amorphous. The first three consisted of one substance, containing C 36·69%, H 3·79%, Ba 27·92%; $C_{15}H_{16}(SO_3)_2Ba$ requires C 36·46%, H 3·24%, Ba 27·84%.

The molecular weight of the aromatic hydrocarbon recovered from the fourteenth fraction of kerosene was determined by the cryoscopic method in glacial acetic acid solution. Two experiments, each involving two determinations, gave a mean value of 143. This is much lower than that calculated from the estimation of barium in the second crop of the barium sulphonate—viz., 195. Perhaps the hydrocarbon is not so pure as the barium salt.

Oxidation with permanganate in aqueous solution was incomplete, but gave a small quantity of a product resembling β-naphthoic acid. Oxidation in acetone solution also gave no definite results.

The theoretical quantity of picric acid dissolved in boiling benzene, calculated on the formula $C_{15}H_{18}$, was added to 2 g. of the hydrocarbon. The picrate on recrystallisation from alcohol had m.p. 108°–110°. The picrate of β-isoamylnaphthalene—a hydrocarbon of the formula $C_{15}H_{18}$—melts at 110°. This, together with the results of the analysis of the barium sulphonate and the character of its oxidation product identifies the hydrocarbon as β-isoamylnaphthalene.

The petrol.

B.O.C. Petrol was distilled with the same 8-pears Young's fractionating column and two fractions were collected at 95° and 122°, using Thole's "cutting" temperatures (J., 1919, 39 T). Of these, the second fraction was already examined by one of us for the manufacture of T.N.T.; and found to contain 21·2% of toluene.

First fraction. The fraction collected by distilling the petrol containing approximately 10% of aromatic hydrocarbons, on nitration yielded a product, which from its b.p. range appeared to consist of nitrobenzene, with a larger quantity of nitrotoluene. Reduction of the nitro compound with tin and hydrochloric acid yielded a product resembling aniline in odour, and consisting of a mixture of aniline and toluidine, as indicated by the b.p. ranges, the production of a violet colour changing to dark red on treatment with bleaching powder solution and ether, and an acetylation test.

The third fraction or residue was found by Thole's process to contain 12% of aromatic hydrocarbons. It was expected to contain the xylenes, as the first large fraction of the kerosene had been found to contain a large proportion of *m*-xylene.

Trinitration, effected as in the case of the fifth kerosene fraction, gave only a small yield of trinitro-compound, and the first crop of crystals from alcohol had m.p. 236°; the nearest to this is 232°, the m.p. of trinitromesitylene. The next two crops had indefinite melting points, even after recrystallisation from alcohol, ranging between 176° and 184° and 140° and 156° respectively.

Sulphonation with an equal volume of cold 98% sulphuric acid gave a product of which the crystalline barium salt contained 37·50% Ba; $C_8H_7(SO_3Ba)_3$ requires 36·95% Ba. This shows the presence of a hydrocarbon of the order of xylenes.

It was felt necessary at this stage to isolate and oxidise the aromatic hydrocarbons. 350 c.c. of the residue from the distillation of one litre of petrol were sulphonated as above, and the aromatic compounds recovered by means of superheated steam. The product (31 g.) was distilled and three fractions collected, viz., 134°–150° (mostly 134°–142°), 19 c.c.; 156°–160°, 9 c.c.; residue, mostly below 170°, 7 c.c. Thus more than half the bulk distils at a temperature range corresponding with the boiling points of the xylenes, viz., 139°–142°. There is also evidence of the presence of higher homologues like mesitylene (b.p. 163°), the trinitro compound of which was detected in the product of polynitration.

To ascertain whether the hydrocarbon C_8H_{10} was one of the xylenes or ethylbenzene, the first fraction of the aromatic hydrocarbons was oxidised by means of chromic acid. A smell of benzaldehyde was detected at first, but the oxidation product was mainly *p*-phthalic acid mixed with a little *o*-phthalic acid—the former being identified by its infusibility, and the formation of a methyl ester of m.p. about 140°, the latter being identified by the resorcinol test.

Thus the main aromatic hydrocarbon of this fraction seems to be *p*-xylene mixed with a little *o*-xylene and an appreciable quantity of mesitylene and some other higher-boiling homologues.

Conclusions.

The Burmah Oil Co.'s petrol and kerosene contain on an average about 10% of aromatic hydrocarbons, which can be separated from the aliphatic portion by sulphonation and distillation with superheated steam, and the residues used for burning and illuminating purposes as usual.

The main constituents of these aromatic hydrocarbons are:—

Benzene, which is present in the petrol and the lowest-boiling fraction of the kerosene.

Toluene, which forms more than 7% of the petrol, and is the main constituent of the aromatic hydrocarbons therein.

The xylenes, all the three isomerides of which are present in the higher fraction of the petrol and the lower fraction of the kerosene, *o*- and *p*-xylenes forming about 2% of the petrol and *m*-xylene about 1·1% of the kerosene.

p-*Cymene*, the main aromatic hydrocarbon of the kerosene, forming 20% of the total aromatic compounds, and thus approximately 2% of the kerosene.

β-Isoamylnaphthalene, which is the main aromatic constituent of the higher fractions of the kerosene, forming 10% of the total aromatic compounds and thus 1% of the kerosene.

In addition to these, mesitylene and cumene have been found in the higher fraction of the petrol and the lower fraction of the kerosene respectively.

The most important of these hydrocarbons, from an industrial point of view, looking also to the proportions in which they are present, would be toluene in the petrol fraction and *p*-cymene in the kerosene fraction. One of us has shown the commercial possibility of this toluene for the manufacture of T.N.T. in a previous paper. The utility of *p*-cymene in the manufacture of thymol and synthetic essential oils is well-known.

Attention must be drawn incidentally to the work started by Gordon and his collaborators (J., 1923, 105 T).

THE PREPARATION OF CYANOACETIC ESTER (ETHYL CYANOACETATE).

BY OSWALD C. STEPHENS, M.SC.

Cyanoacetic ester is usually prepared by the esterification of cyanoacetic acid, made by the action of potassium cyanide on chloroacetic acid. The discovery by Imbert (G.P. 212,592) of a method for preparing chloroacetic ester directly without the previous isolation of chloroacetic acid, suggests the possibility that the preparation of cyanoacetic ester direct from chloroacetic ester may be a more useful and less laborious operation.

The preparation of cyanoacetic ester from trichloroethylene and otherwise has been investigated and is described in this paper in three stages:

1. A quantitative investigation of the preparation of chloroacetic ester by Imbert's method.

2. An investigation of the preparation of cyanoacetic ester from chloroacetic ester.

3. A study of alternative methods of preparing cyanoacetic ester.

The preparation of chloroacetic ester.

Tompkins (J., 1907, 167) showed that when trichloroethylene is treated with a hot solution of sodium or potassium ethoxide in ethyl alcohol, dichlorovinyl ether is formed, and Imbert (*loc. cit.*) later discovered that if this dichlorovinyl ether is heated with alcohol to which a trace of anhydrous aluminium chloride is added, chloroacetic ester is formed.

The preparation of the dichlorovinyl ether is best effected as follows.

To 83 g. of trichloroethylene in 150 c.c. of absolute alcohol, are added in small quantities, 11·5 g. of sodium dissolved in 90 c.c. of absolute alcohol, the mixture is warmed to 65°–75° to start the reaction, and stirred vigorously, the reaction being allowed to moderate before adding further quantities of ethoxide and the mixture cooled before each addition. If the temperature is allowed to rise much above 70° the reaction may be very violent. The mixture is boiled on the water-bath for one hour after all the ethoxide has been added, poured into water, the vinyl ether is separated, dried over calcium chloride and distilled, the fraction distilling at 122°–126° being collected as dichlorovinyl ether (17 g. of trichloroethylene were recovered and 58 g. of dichlorovinyl ether obtained 81% yield calculated on trichloroethylene consumed).

The effect of using an excess of trichloroethylene is to minimise the formation of reduction products. In earlier experiments the theoretical quantity of trichloroethylene was added to the sodium ethoxide in alcohol and the mixture cautiously warmed on the water-bath. The reaction was very vigorous, necessitating cooling, and, in addition, a spontaneously inflammable and explosive gas, probably monochloroacetylene, was formed in small quantity (Wallach, J. Chem. Soc., 1878, 653).

Conversion of dichlorovinyl ether into chloroacetic ester.

The ether is converted into chloroacetic ester by boiling with ethyl alcohol to which a trace of anhydrous aluminium chloride has been added (Imbert, *loc. cit.*). The reaction once begun is very vigorous and ethyl chloride is given off in quantity. Owing to the vigour of the reaction a specially wide reflux condenser is necessary. The ethyl chloride can be collected in a suitable condensing apparatus. 75 g. of dichlorovinyl ether and 70 c.c. of absolute alcohol yielded 55 g. of chloroacetic ester (88·7% yield). A further experiment gave a 90% yield.

The use of rectified spirit in place of absolute alcohol in the conversion, lowered the yield of ester by 13%, and, in addition, a quantity of hydrogen chloride was formed as well as ethyl chloride (*cf.* Crompton and Vanderstichele, Chem. Soc. Trans., 1920, **117**, 691).

It is not possible to recover the alcohol from the dichlorovinyl ether by fractional distillation, as a considerable amount of the ether distils over with the alcohol even with a three-section still-head. The conversion into chloroacetic ester can, however, be effected without separating the vinyl ether from the original reaction mixture, and, after conversion, the alcohol can be recovered by fractional distillation at reduced pressure. 166 g. of trichloroethylene ($1\frac{1}{4}$ mols.) to which were added 23 g. of sodium in 340 c.c. of absolute alcohol, gave 98 g. of chloroacetic ester, and 34 g. of trichloroethylene were recovered. Calculated on trichloroethylene consumed, this is an 80% yield. In other experiments yields of 79% and 76% were obtained.

As the trace of alkali present may cause the aluminium chloride to lose its activity, a further addition of catalyst towards the end of the reaction may be necessary.

Preparation of cyanoacetic ester from chloroacetic ester.

The preparation of cyanoacetic ester from chloroacetic ester seems very straightforward, and Muller

(J. Chem. Soc., 1864, 109) stated that this was the most satisfactory way of obtaining cyanoacetic ester. It is found, however, that when chloroacetic ester and potassium cyanide react in alcoholic solution a quantity of material of higher boiling point is obtained. The explanation of this is found in the work of Haller (J. Chem. Soc., 1888, 937) and Zelinsky (Ber., 1888, 3398), who showed that chloroacetic ester in reacting with potassium cyanide gives a monopotassium derivative which reacts with more chloroacetic ester giving cyanosuccinic ester and cyanotricarballylic ester. The low yield of cyanoacetic ester is largely due to the formation of these secondary products, the production of which is accompanied by a great darkening in colour owing to the formation of azulmic acid (Zelinsky, *loc. cit.*).

The reaction was carried through as follows: To the chloroacetic ester dissolved in alcohol the cyanide was added, and the whole boiled on the water-bath under a reflux condenser until the reaction was completed. The alcohol was distilled off at reduced pressure, the residue poured into water, and the cyanoacetic ester separated. The aqueous layer was then extracted with ether, and the ether extract added to the separated ester. This is necessary as cyanoacetic ester is difficult to separate from water containing even a small quantity of alcohol. The ether was distilled off and the residue fractionated at reduced pressure, the fraction distilling at 95°–102° at 14 mm. being collected as ester. 41 g. of chloroacetic ester, refluxed with 19 g. of 94% sodium cyanide in 100 c.c. of absolute alcohol for four hours, gave 12 g. of cyanoacetic ester (30% yield).

Other cyanides (sodium silver cyanide, sodium cuprous cyanide, mercuric cyanide, and lead cyanide), possible from an industrial standpoint, were tried in the hope of obviating the formation of these secondary products, but all gave negative results.

As the cyanoacetic ester competes with the chloroacetic ester for the sodium cyanide and so reduces the yield, the relative concentration of the chloroacetic ester was increased by taking only half the theoretical amount of sodium cyanide. Also, as the darkening due to the formation of azulmic acid indicated the condensation of the cyanoacetic ester with the chloroacetic ester, the action was stopped when the dark colour became at all pronounced. Under these conditions 81 g. (2/3 mol.) of chloroacetic ester with 17 g. (1/3 mol.) of sodium cyanide in 100 c.c. of absolute alcohol boiled for 90 minutes on the water-bath gave 18 g. of cyanoacetic ester, and 9 g. of high-boiling product, and 43 g. of chloroacetic ester were recovered. The yield calculated on chloroacetic ester consumed is 51%.

By the addition of the cyanide in small portions it was hoped that, by thus still further increasing the relative concentration of the cyanoacetic ester, the cyanide would react more quickly and, owing to its rapid removal, the cyanoacetic ester formed would not be able to condense with the excess of chloroacetic ester.

Using the same quantities as in the previous experiment, 25 g. of cyanoacetic ester were obtained, 11 g. of high-boiling product and 37 g. of chloroacetic ester being recovered. This yield is 61%. The use of an efficient motor stirrer to avoid any local excess of cyanide gave similar results. The effect of very finely divided cyanide was tried as possibly giving a quicker reaction, but was no more satisfactory. With the same quantity a 60% yield was obtained.

It was thought that bromoacetic ester, being more reactive towards sodium cyanide than chloroacetic ester, should give a quicker reaction, thus avoiding the formation of the more complex products. It was, however, no improvement.

The important point in this preparation seems to be to bring about as vigorous a reaction as possible between the ester and the cyanide. The reaction in absolute alcohol is slow, as sodium cyanide is only slightly soluble in absolute alcohol. It seemed possible that, if the cyanide were dissolved in the least quantity of aqueous spirit, the action would be vigorous and complete, and thus the more complex products would not be formed.

To 42 g. of chloroacetic ester dissolved in 70 c.c. of rectified spirit and 20 c.c. of water, 8·5 g. (½ theory) of sodium cyanide were added, and the flask was warmed on the water-bath until the reaction commenced. The reaction was very vigorous, and ebullition went on for some time after the flask was immersed in cold water. After boiling for one hour the cyanoacetic ester was separated as described previously. 12 g. of cyanoacetic ester and 2 g. of high-boiling products were obtained, and 13 g. of chloroacetic ester were recovered.

The yield calculated on cyanide taken is 66%: calculated on chloroacetic ester consumed, 47%. This loss of chloroacetic ester was probably due to hydrolysis to glycollic ester.

(To be concluded.)

THE ACTION OF SALT SOLUTIONS ON IRON AND STEEL IN THE PRESENCE OF OXYGEN.

BY U. R. EVANS.

The effect of various salts on the corrosion of iron and steel by water in the presence of oxygen has been studied by Heyn and Bauer,[1] Friend and Brown,[2] Friend and Barnet,[3] as well as other investigators. In these researches, plates of metal were immersed below the surface of water, whilst other similar plates were immersed in a similar position below the surface of solutions of various salts made up with the same water; after a considerable period, the amount of corrosion was ascertained (by determining the loss of weight), and by comparing the figures obtained, the effect of the various salts was arrived at.

Clearly, however, the process of corrosion, under such conditions, consists of two separate stages —

(*a*) The transport of oxygen from the air through the liquid to the metal, either by diffusion, convection, or both;

(*b*) The consumption of oxygen, directly or indirectly in the corrosion of the metal.

Usually the addition of a salt to water will be unfavourable to stage (*a*) owing to a decrease in the oxygen-solubility, an increase in viscosity, and other causes. Often, however, it may stimulate stage (*b*), the corrosion process proper. Obviously if the specimen is very deeply immersed in liquid, the results will mainly show the effect of salts upon the transport of oxyen; if it is merely covered with a film of liquid so thin as to be perpetually saturated with oxygen, the results indicate, to some extent at least, the specific effect of the salt on the corrosion proper. Heyn and Bauer, as well as Friend and his colleagues, used intermediate conditions, and their results are therefore difficult of interpretation. In many cases, Friend found that the addition of small amounts of salts increased the corrosion, but larger amounts again reduced it. As would be expected, the curves connecting corrosion-rate with concentration vary with the condition of immersion; Heyn and Bauer's curves, for instance, do not agree with those obtained by Friend and his collaborators. Moreover, whilst Friend[4] has shown that the addition of 3% of sodium chloride to distilled water actually reduces the corrosion of deeply immersed specimens of iron, the present author[5] has shown that if the action of shallow drops of 3% sodium chloride solution is compared with that of similar drops of distilled water, the rusting is far quicker in the case of the salt solution. Apparently sodium chloride is unfavourable to stage (*a*), but favourable to stage (*b*) of the process.

The more destructive types of corrosion are now known to be of an electrochemical character. The direct attack of oxygen upon a metal usually leads to the production of a compact oxide film *in situ* which, being in mechanical contact with the metal, interferes with further attack, producing ennoblement or protection. On the other hand, indirect electrochemical action, although often finally leading to the formation of an insoluble oxide or hydroxide, usually causes it to be produced by precipitation at a sensible distance from the surface, where it does not necessarily put a stop to further corrosion. For example, in the attack of sodium chloride solution on iron, ferrous chloride is produced at the anodic portions, and alkali at the cathodic portions; both these substances are soluble, although where they meet, they will produce the sparingly soluble ferrous hydroxide (oxidising to ferric hydroxide); this will usually occur at an appreciable distance from the surface of the metal, and the precipitate will have a non-compact, non-protective form.

It was, until recently, believed that the distribution of cathodic and anodic areas depended only on the distribution of impurities in the metal. It is undoubtedly a fact that, if the distribution of oxygen over the surface is uniform, such substances as the carbide, phosphide, sulphide, and oxide of iron (and particularly graphite, if present) do tend to act as cathodes towards the grains of pure α-iron, which become anodes.[6] But the present author[7] has shown that under ordinary conditions, it is mainly the distribution of oxygen which dictates the polarity of different parts of the surface. Thus if two strips of iron joined to a galvanometer are placed in sodium chloride solution in a divided cell, and air is bubbled over one strip only, an electric current is produced at the expense of the unaerated electrode, which serves as the anode or attackable pole. We thus arrive at an explanation of the specially rapid corrosion observed at just the places to which oxygen has no direct access; for instance, it is possible to understand the localised corrosion seen at points where metallic specimens are supported through contact with glass, porcelain, thread or other material; it is easy to account for the rapid pitting observed in crannies and the localised corrosion produced where porous débris settles on a metallic surface —cases which cannot be explained on any view which regards corrosion as a phenomenon of direct oxidation.

Corresponding results were obtained by the author[8] by the study of drops of water or salt solution placed on a sheet of clean iron. Here the peripheral portion at the edge of the drop, to which oxygen has direct access, becomes ennobled and cathodic, whilst the interior portion to which oxygen can diffuse less readily becomes the anode; corrosion occurs, therefore, only at the centre, not round the edge. The

present paper describes a more detailed study of the action of drops of solutions of different salts on iron, with special regard to the factors which cause some salts to stimulate corrosion and others to reduce it. It is easy to see why salts like sodium chloride, which yield soluble products both at cathode and anode, stimulate corrosion. Three cases, however, suggest themselves where salts might actually reduce the rate of attack of the water to which they are added :—

(*a*) Salts which yield, as the anodic product, an insoluble iron salt, in a compact and protective form, which is able to put a stop to further anodic attack.

(*b*) Salts which yield, as the cathodic product, a porous, non-conducting, insoluble substance, which (whilst unable itself to act as cathode) will interfere with the diffusion of oxygen to the metal below.

(*c*) Oxidising agents which can produce a protective layer over the parts to which oxygen itself cannot diffuse, and thus produce passivity beneath the central part of the drop, as well as in the peripheral portions.

The results of the research seem to provide examples of all three classes of salts.

Materials and experimental method.

The material used in the experiments specifically described below was a steel sheet containing 0·39% of carbon. Experiments were also conducted with annealed sheets of low-carbon steel, such as is employed in tin-plate manufacture, and also with "Armco" iron, a soft iron comparatively free from carbon, and containing less than 0·16% of total impurities. The phenomena observed with both materials were qualitatively the same as those met with in the 0·39% carbon steel.

Immediately before use the sheets were rubbed several times in each direction with coarse emery paper (Oakey's "$1\frac{1}{2}$" quality), washed with distilled water, dried with filter-paper, re-ground with emery to give an entirely new surface, and again wiped. They were then cut into convenient sizes (2 cm. squares in the quantitative experiments) and the drops dropped from a height of 3·4 cm. from a pipette (the same pipette was used through the research). This gave a drop of diameter about 1 cm., and volume 0·05 c.c.

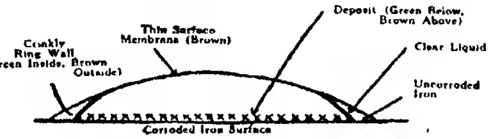
The distilled water used in the experiments was that used in the laboratory for conductivity purposes, and was condensed in block-tin, and collected in a flask which had been used for the purpose for some years, closed with a soda-lime tube. The early distillates were rejected, but finally a sample of 2 litres was collected for use in the "distilled water" experiments; the sample was employed in the preparation of the solutions used in the quantitative work. Ordinary laboratory distilled water gave qualitatively the same phenomena.

To prevent evaporation of the drops, the early experiments were conducted in a "water-sealed vessel" made by placing a glass plate $6\frac{1}{2}\times4\frac{3}{4}$ in. on four cork legs on the floor of a 10×8 in. developing dish, containing a shallow layer of water ; the square of steel on which the drops had been placed were laid on the glass plate, and a "half-plate" dish wa placed in an inverted position over the whole, thu completely sealing the drops from the externa atmosphere. In this apparatus, the various sample competed with one another for a limited quantity o air, and the temperature was not constant.

Where a constant temperature and a constan supply of air were desirable, a thermostat apparatu was used. The reaction-vessel consisted of a vacuun desiccator, two-thirds filled with water to prevent i floating, and immersed up to the stopper in a ther mostat bath ; the specimens were placed on a hori zontal glass plate, within the reaction vessel, sup ported above the level of the water upon a glas tripod ; the cover of the vessel was luted on witl thick grease. The air was freed from carbon dioxid and ammonia by passage through wash-bottles con taining caustic soda and Nessler solution, and thei bubbled through two wash-bottles containing water the second being placed in the thermostat bath itself Finally the air entered the reaction vessel by a glas tube passing down through the stopper and wa bubbled through the water in the lower part of th vessel itself. It passed out of the reaction vesse through an ordinary trap. The object was to insur that the air which passed through the reaction vesse was approximately saturated with water vapour, i order that its passage through the vessel should no tend to cause evaporation of the drops.

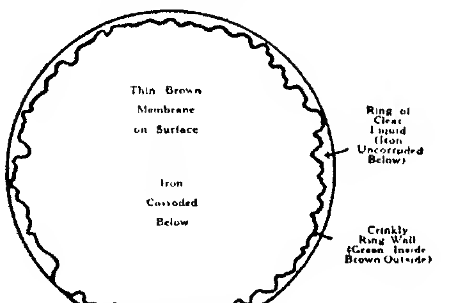
Results obtained with water and different solutions.

Action of distilled water. After being placed on iro for one night (either at 29°, or at ordinary tem



Distilled water, section.

FIG. 1.



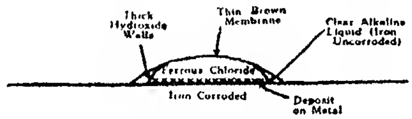
Distilled water, plan.

FIG. 2.

perature) drops of distilled water show the phenomen illustrated diagrammatically in Figs. 1 and 2. crinkly ring (brown on the outside, dark green on th

ide) occurs all round the drop very close to the dge, and a thin brown membrane extends over the op of the drop; outside this membrane there is a arrow ring of liquid, below which the metal is quite nattacked. Within the membrane the steel is dis-inctly corroded; the ground of the metal is also vered with a loose deposit, green below and brown bove.

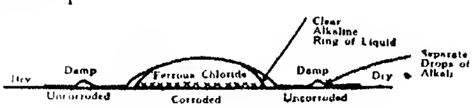
The probable explanation is as follows. Close to he edge of the drop where oxygen has direct access the metal, the direct production of an oxide film curs, which, being formed *in situ*, is protective; efore it has reached the thickness sufficient to show



Potassium chloride, first stage, section.

FIG. 3.

he first interference-tint, this film ceases to grow urther. Naturally the protected (ennobled) iron is athodic towards the iron in the centre of the drop, o which oxygen does not diffuse so readily. There-ore, anodic attack will proceed everywhere except ust around the margin of the drop, and this attack will produce ferrous hydroxide—a substance, which, s pointed out by Whitman, Russell, and others, has very perceptible solubility.[9] Where the ferrous hydr-xide comes in contact with diffusing oxygen, it is xidised first to the green intermediate oxide, and hen to the brown ferric hydroxide (or hydrated xide); these compounds are much less soluble, and will ppear as a precipitate (or perhaps to some extent n colloidal solution), and since they are formed, not *n situ*, but at an appreciable distance from the netal, they will not be protective or closely adherent. A large quantity is formed close to the surface of the netal, and by its formation helps to absorb diffusing xygen and thus to keep the surface below it anodic. There is naturally a special amount of ferric hydroxide ormed close to the edge at the junction between the erated and unaerated areas, and also over the surface f the drop.



Potassium chloride, second stage, section.

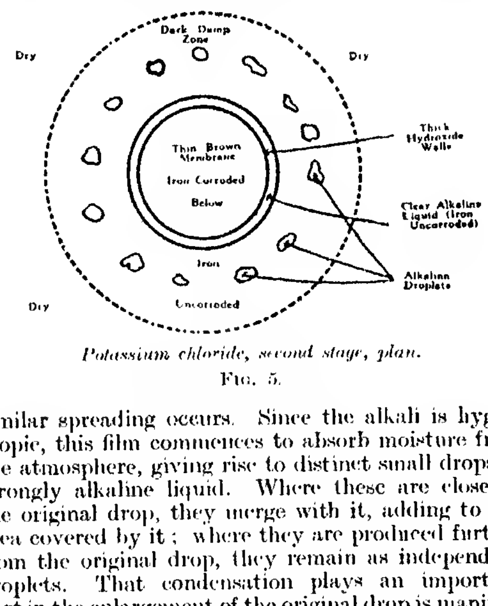
FIG. 4.

Action of N/10 potassium chloride. Drops of this solu-tion placed on iron or steel give—as shown in previous papers—ferrous chloride in the central (anodic) portions, and alkali in the peripheral (cathodic) por-tions. A ring of white cloudy ferrous hydroxide appears where the ferrous chloride and alkali meet, and this soon turns brown; finally a complete but thin membrance of ferric hydroxide covers the top of the drop (Fig. 3).

[9] According to W. G. Whitman and R. P. Russell (J., 1924, 193T), ferrous hydroxide is sufficiently soluble to alter the p_H value of water from p_H 7 to p_H 9·5.

The most remarkable feature of the action is that the drop tends to spread during the corrosion process. Five drops having an initial diameter of 0·9 to 1·0 cm. were placed on steel; after a few hours each drop (Figs. 4 and 5) was surrounded by a circular patch of moisture upon the metal; over this patch the metal was covered with a thin film of alkaline liquid, and assumed a darkish appearance due to the dampness; a ring of small drops of alkaline liquid (about 0·07 cm in diameter) surrounded the large drop. The metal was quite uncorroded over this outer area; all the corrosion which had occurred was confined to the portion within the membrane. The diameter of the dark, damp circle was about 1·3 to 1·4 cm. after 3 hours, and 1·8 to 2·0 cm. after 24 hours.

The cause of the spreading was clearly due to the formation of alkali. It is easy to show that a drop of caustic alkali placed on emery-treated steel imme-diately spreads itself out over the surface as a thin film. When, therefore, a drop of potassium chloride solution is placed on steel, as soon as any serious amount of alkali has been formed at the edges a



Potassium chloride, second stage, plan.

FIG. 5.

similar spreading occurs. Since the alkali is hygro-scopic, this film commences to absorb moisture from the atmosphere, giving rise to distinct small drops of strongly alkaline liquid. Where these are close to the original drop, they merge with it, adding to the area covered by it; where they are produced further from the original drop, they remain as independent droplets. That condensation plays an important part in the enlargement of the original drop is manifest from the fact that the enlargement was much less marked in the experiments conducted in the ther-mostat than in those carried out at variable temperature.

The production of multiple membranes was fre-quently observed, and is a natural consequence of the spreading. In the early stages, the portion of the iron just within the edge of the drop itself is cathodic, and the first hydroxide wall is in the position indicated in Fig. 3. When the thin film of alkaline liquid has been formed over the surrounding iron (Fig. 4), this represents a portion far more accessible to oxygen than any part covered by the drop proper; consequently the whole part below the drop now becomes anodic and a fresh membrane appears, roughly covering the area of the original drop

(Fig. 6). The gradual extension of the liquid outwards causes the formation of wrinkles on the thin membrane covering the original drop.

The formation of this thin membrane over the top of the drop was the subject of special experiments. When a portion of the liquid from the inside of the membrane was withdrawn by means of a glass tube drawn out to a fine point, and placed on a glass plate, no fresh membrane appeared over the surface. This showed that the membranes formed upon drops placed on iron do not represent an oxidation product of the anodic ferrous chloride, but are produced by the precipitation of that salt by the alkali formed in the peripheral portions.

Potassium chloride, third stage, section.

FIG. 6.

When the thin membrane over the top of the drop is washed away by a gentle stream of water, so as to leave the truncated remains of the circular wall, it is seen that—in addition to the formation of the membranous hydroxide—the ground of the centre of the drop is covered with a thin, dark deposit (brown on the top and green below), beneath which the steel is distinctly corroded. The deposit is probably not a direct anodic product, since it is quite loose, and can be rubbed away readily with the fingers. It is probable that since the solution contains OH' ions in addition to Cl' ions, a certain amount of ferrous hydroxide is produced anodically, as well as ferrous chloride; this yields the green and brown deposit by oxidation, and the change itself helps to prevent access of oxygen to the metal below.

Action of N/10 (M/20) potassium sulphate and N/10 potassium nitrate solutions. Drops of these solutions gave results which were almost exactly similar to those obtained with potassium chloride; the formation of the ring of hydroxide, developing into a membrane, and the spreading out of the drop as a dark, damp patch with independent small droplets of alkaline liquid were plainly shown.

Quantitative experiments with distilled water and potassium chloride, nitrate, and sulphate. Although—owing to the familiar variation which occurs from point to point on all samples of sheet-metal in regard to susceptibility to rusting—it seemed hopeless to expect that all the drops of a given liquid would develop exactly the same amount of corrosive action, it seemed worth while to carry out some quantitative determinations on the amount of iron rusted by drops of different solutions. Three series of experiments were carried out in a thermostat at 29·2°, one for 5½ hours, one for 18½ hours, and one for 48¾ hours; these "nominal" times were measured from the instant of placing of the specimens in the thermostat, and no account was taken of the initial time taken in placing the drops on the metal; the initial disturbance due to this cause, together with the time required to bring the specimens to the temperature of the thermostat, must be borne in mind in comparing the results of the three series of experiments. In each series, four squares of metal were exposed to each of the four solutions used, making 16 squares in all. When the vessel was opened at the end of the experiment, each drop (and the rust contained in it) was washed into a test-tube, a glass rod with rounded end being used to loosen the corrosion-product; 2 c.c. of dilute hydrochloric acid were added to each tube and, after dissolution was completed by warming, hydrogen peroxide was added, and the whole heated until oxygen ceased to be evolved. The liquid in each tube was made up to 250 c.c., and 5 c.c. were then drawn out and added to 1 c.c. of 10% pot sium thiocyanate; in another vessel 1 c.c. of 1(potassium thiocyanate was placed, and standard ir solution (1 c.c. = 0·01 mg. ferric iron) was run in match the colour, water being added to both vess to give an appropriate dilution; the requisite num of c.c., divided by 2, gave the number of milligra of iron in the drop in question.

The results obtained were:—

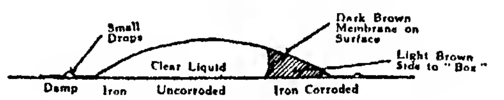
Owing to the expected variation between the amounts of iron oxidised by drops of the same liquid—especially in the longer period experiments—it is impossible to draw very exact conclusions. But there is no doubt that all three salts, in the concentrations employed, very distinctly stimulate corrosion, and that there is no very marked difference between the stimulating power of the three.

Action of N/10 (M/20) sodium carbonate. Man of the drops of sodium carbonate solution place on steel produced no visible alteration after a few days at ordinary temperature; the drops

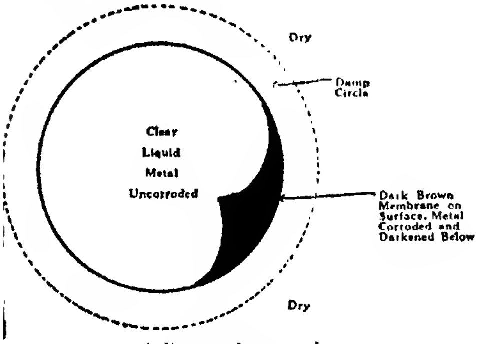


Sodium carbonate, section.

FIG. 7.

remained clear and colourless, and the metal surface was bright and unchanged. Occasionally, however, at some one point within a drop, marked local attack would take place, although elsewhere over the surface in the same drop, the metal was unchanged; from this one point, the attack would gradually extend outwards, as described below. Wherever local attack occurred anywhere within a drop, marked spreading of the liquid was observed all round the

ge of that drop, no doubt owing to the formation lkali hydroxide (Figs. 7 and 8); there was no ading at the edges of those drops within which local attack took place.



Sodium carbonate, plan.
FIG. 8.

Only a fraction of the drops of $N/10$ sodium bonate solution caused local attack in the manner cribed within the period of the experiment; the bility to local attack, however, increased considery when the solution was diluted. In the following periment, drops of solutions of 9 different concentions (12 drops of each) were placed on steel sheet the water-sealed vessel, and were uncovered and amined at the intervals shown below.

The number of drops of each concentration which showed local attack at each examination is indicated n the following table:—

oncen-ration.	No. of drops showing local attack after 1 hr.	2 hrs.	3 hrs.	4 hrs.	5 hrs.	6 hrs.	7 hrs.	8 hrs.	24 hrs.	48 hrs.
·1 N	0	0	0	0	0	0	0	0	0	0
·09 N	0	0	0	0	0	0	0	0	0	0
·08 N	0	0	0	0	0	0	0	0	1	2
·07 N	0	0	0	0	0	0	0	0	4	6
·06 N	0	0	0	2	2	2	2	2	8	10
·05 N	0	1	4	8	9	9	10	11	12	12
·04 N	0	3	0	12	12	12	12	12	12	12

·01 N	12	12	12	12	12	12	12	12	12	12

Total number of drops of each concentration - 12.

Not only does the initiation of local attack occur very much more quickly in the dilute solutions, but the rapidity with which the attack spreads out from the original starting point is much greater where the concentration is lowest.

The initiation of local attack also appears to be favoured by the addition of potassium chloride or other salts. In one experiment ten drops of $N/10$ sodium carbonate, and ten drops of $N/10$ sodium carbonate containing 1/100 of its volume of $N/10$ potassium chloride were placed close together on a sheet of iron in the water-sealed vessel. After $2\frac{1}{2}$ hours, they were examined, and it was found that one drop containing potassium chloride showed local attack; all the others were unchanged. After $3\frac{3}{4}$ hours, 7 out of 10 drops containing potassium chloride showed local attack, but only one out of the 10 free from potassium chloride.

The liability to local attack is not seriously increased by addition of similar small quantities of sodium bicarbonate; on the other hand, drops of the liquid made by mixing equal amounts of $N/10$ sodium carbonate and $N/10$ sodium bicarbonate produced rapid marginal attack; out of 14 drops, 7 showed this phenomenon after $1\frac{1}{2}$ hours, and 12 after 6 hours. To test the effect of carbon dioxide, 20 drops of $N/10$ sodium carbonate were placed on a steel sheet in the water-sealed vessel; after one day only two showed local attack. The sheet was then exposed to a stream of carbon dioxide for two minutes, and was returned to the vessel; after two days it was again examined, but there was no further case of local attack.

Quantitative experiments showed that where no breakdown had occurred, the amount of iron brought into solution in a drop was extremely small. Thus three drops of $N/10$ sodium carbonate, after standing on iron for two days at the ordinary temperature, contained 0·003, 0·008, and 0·004 mg. of iron respectively. Three drops placed on iron at 27°–29° for one day showed a local breakdown in every case, and at the end of the time contained 1·72, 1·50, and 1·75 mg. of iron; this is a larger amount than was obtained with three drops of distilled water in the same vessel (1·0, 1·0, and 1·55 mg.).

In the great majority of cases, the local attack set up in drops of sodium carbonate solution commenced at the edge of the drop, and extended gradually; the area undergoing attack in this case had the form of a triangle with curved sides (Figs. 7 and 8); a triangular dark brown membrane formed over it, on the surface of the drop, whilst the sides were completely cased in by nearly vertical walls of light brown membranous matter. Outside this triangular "box," the steel was quite unchanged; inside the "box," the metal was corroded, and covered with a thin dark grey, rather adherent deposit, which remained even after rubbing.

In a few cases the attack commenced in the centre, and a sack-like cylindrical membrane then arose from the point undergoing change. Drops containing much potassium chloride (made by mixing equal volumes of $N/10$ sodium carbonate and $N/10$ potassium chloride) produced zonal phenomena, recalling those which appear with drops containing potassium chloride alone. The central portion of the steel became covered with a green deposit surrounded by a brown ring, and around the edge was a ring of clear liquid below which the steel was unattacked. Evidently the central (unaerated) portion was anodic, and the direct anodic product was ferrous chloride, yielding both hydroxide and carbonate by precipitation.

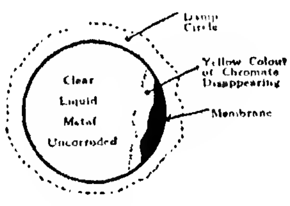
Action of N/10 (M/30) sodium phosphate (Na_2HPO_4). Sodium phosphate behaves in the same way as sodium carbonate, but it is a more efficient inhibitor of corrosion, as the film breaks down less frequently. Four drops placed on steel for 48 hours at ordinary temperature remained at the end of the time quite clear and unaltered; the steel was unchanged in appearance. Analysis showed that the drops contained respectively only 0·004, 0·004, 0·005, and 0·005 mg. of iron.

Three more drops were placed on steel, and exposed in the thermostat at 29·2° for 24 hours. Of these, one showed complete breakdown of the film, and contained 0·65 mg of iron at the end of the period. The other drops produced no apparent change; one contained 0·005 mg. of iron, whilst in the other iron was scarcely detectable.

In another experiment, three drops were kept on steel for a day at 27°–29°, and caused no visible alteration in the metal; the drops only contained 0·005, 0·007, and 0·006 mg. respectively at the end of the test.

Action of N/10 (M/20) potassium chromate. Drops of this solution produced no visible change upon the iron, and the actual amount of iron which passed into solution was very small. Two drops of the solution placed on iron for one day at 27°–29° were found at the end of that time to contain 0·006 mg. of iron each. Evidently the protective film produced is highly efficient.

No local breakdown of this protective layer was ever observed with pure potassium chromate; even the addition of small amounts (1/100 or 1/10 volume) of N/10 potassium chloride produced no failure. However, when drops of a solution made by mixing equal volumes of N/10 potassium chloride and N/10 potassium chromate were placed on iron, brown spots appeared within five minutes, at the extreme edge of the drops (often 3 or 4 spots on each drop), and the brown substance fairly quickly extended inwards over the surface of the drop; after a time it could be seen that a complete "box" had been formed by the iron hydroxide membrane, similar to that produced with sodium carbonate, except that it had a rounded rather than a triangular form



Potassium chromate, plan.

FIG. 9.

(Fig. 9). Inside the box, the liquid contained ferrous salts, and the iron was notably attacked; outside the box there was no attack upon the iron, and the liquid remained clear, but near the advancing edges of the box, the yellow colour of the chromate disappeared, indicating probably that the chromate, and not merely dissolved oxygen, was acting as the oxidising depolariser at the cathodic places. In some cases, the attack commenced not at the edge but at some point in the centre, the cylindrical form of "box" being produced.

It was noticed that where a mixture of chromate and chloride was placed on a sheet of steel covered with small rust spots, marked local attack often occurred below the rust, through which pale brown tumours of hydroxide grew up rapidly. Possibly the chromate failed to diffuse rapidly through the porous rust; if so, the conditions below the rust would become ideal for anodic attack.

The addition of an equal volume of N/10 potassium nitrate to N/10 potassium chromate was also found to be capable of producing marginal breakdown, but the attack spread inwards very much less quickly than where potassium chloride was used. Solutions containing potassium sulphate along with potassium chromate acted still more slowly. After 24 hours there were only tiny brown specks on the edges of the drops, although drops containing an equivalent concentration of chloride had in some cases become half-covered with membrane within this time. In all cases of "breakdown," spreading was noticed; where there was no breakdown, there was no spreading.

Cause of local breakdown of protective films. It is not difficult, in a general way, to offer an explanation of the behaviour of sodium carbonate, phosphate and chromate. In a drop of potassium chromate a protective film will at once be produced by direct chemical oxidation, and will inhibit electrochemical action. In a drop of sodium carbonate, or phosphate, electrochemical action may commence momentarily, but the anodic product will be insoluble, and if it is adherent the anodic action is likely soon to become very slow; even if the anodically produced skin is not itself entirely protective, oxygen diffusing to the surface is likely to render complete the passivity.

But now suppose that at one place the protective film fails to adhere to the metal, but forms a loose porous diaphragm over it, the contrary result will be produced. The diaphragm will shield the underlying surface from oxygen, and thus stimulate the continuance of anodic attack; the shielding of the metal from oxygen will be partly mechanical, but, since ferrous carbonate is an oxygen-absorbent, it will also be partly chemical. Furthermore, to some extent, a loose, porous skin may act as a semi-permeable membrane, and the concentration of sodium carbonate, sodium phosphate, or potassium chromate below it may soon come to be less than in the main portion of the drop; if so, a considerable amount of the comparatively soluble substance ferrous hydroxide, will be formed as the immediate anodic product, although it will be converted into ferric hydroxide, carbonate, or phosphate further out from the place of formation; if the solution contains chlorides, the freely soluble ferrous chloride will be formed as the anodic product, and this fact represents one reason why the presence of chlorides facilitates the local breakdown of the film. It must also be remembered that many other protective films (*e.g.*, the oxide film formed on an aluminium anode polarised with an external E.M.F.) are pervious to Cl′ ions, and tend to break down in the presence of chlorides. Iron provides an analogous case; chlorine ions readily cause local breakdown of the film, NO_3' ions appear to be distinctly less effective in piercing the protective layer, and SO_4'' ions have still less power to produce that result.

It is clear, therefore, that if at any point the film once becomes non-adherent, anodic attack is likely to be stimulated—rather than obstructed—

that point, and corrosion, when once initiated, ll continue apace; from this point, the loosening the film, and therefore the area susceptible to odic attack, may gradually extend. We have ill to consider what might cause the skin locally become porous or non-adherent. As pointed out the author in previous papers,[10] the manner in hich the corrosion-product will cling to the surface ll be determined largely by the relative values of e interfacial energies between the metal, liquid, d corrosion-product; even where the corrosion-oduct is normally protective, some local peculiarity the surface of the metal may easily cause a change the character of the adhesion. Particularly is this ange expected to occur at the edge of the drop, ere (as suggested by Bengough and May[11]) the rrosion-product may sometimes adhere to the -liquid interface instead of to the liquid–metal erface; it is significant to notice that, in the at majority of cases, local attack does actually mmence at the edge of the drops.

It was thought that possibly the presence of grease ght increase the chance of non-adhesion; but tempts to increase the liability of the metal to local eakdown by means of the application of vaseline ve negative results. It was also thought that possibly particles of metallic dust might be the cause of e breakdown; but experiments showed that parts a sheet which had not been "wiped" after the al grinding with emery were no more susceptible local breakdown than those which had been oroughly freed from dust with filter-paper. The tion of rust in stimulating local action in mixtures chloride and chromate has already been referred to; seems possible that sub-microscopic crannies of such rrow dimensions as to allow chlorides to enter more adily than chromates, carbonates, or phosphates ight act in the same way.

Sodium carbonate, sodium phosphate, and potassium chromate have all been used in anti-corrosive eparations, water-treatment mixtures, boiler compounds, etc. All these salts greatly reduce corrosion long as there is no breakdown in the protective film oduced; but they produce localised corrosion (the ost dangerous of all types) in the event of a breakdown. Such results serve to explain the distinctly ntradictory statements often found in literature garding the effect of these substances on corrosion, d show how carefully any process of corrosion-revention which depends on the formation of a protective film must be tested, before it is put into technical use; a comparatively small alteration in conditions (*e.g.*, the access of chlorides, or the presence of air-space) may sometimes greatly increase the robability of a film-breakdown. Chromates seem produce a much more reliable protective film than rbonate or phosphates, but in the event of local reakdown the corrosion may be very rapid, since in e presence of chromates it will not be limited by e rate of supply of oxygen.

Action of N/10 (M/30) potassium ferricyanide. Drops of this solution placed on steel turned slightly greenish after a day, but remained clear and without visible action on the metal. On washing away the solution, a very thin, pale blue film was left over the area occupied by the drop (barely visible until the specimen was held in a favourable position to the light). This film was sufficiently adherent to resist the action of a water-jet, but could be largely rubbed off with filter-paper; the film consisted of Prussian blue. In addition, there were in some cases a few more distinct spots of blue at the edge of the drop, suggesting local breakdown of the protective film.

The addition of a trace of chloride greatly promotes the action of ferricyanide on iron and steel. A $N/10$ solution of potassium ferricyanide to which 1/100 volume of $N/10$ potassium chloride had been added, turned green within 2 minutes of being placed on the iron surface. After a day the centre of the drop was full of a blue, stringy precipitate, whilst around this there was a brown coloration due to a smaller amount of a fine precipitate (no membrane); at the edge of the drop the liquid was perfectly clear. A good deal of spreading was noticed, indicated by the formation around the original drop of a dark, damp circle with small droplets on it. Here we evidently have an ordinary case of electrochemical attack; at the edges (aerated) the cathodic product is alkali, which causes the spreading, whilst in the interior, the immediate anodic product is ferrous chloride, which yields ferrous ferricyanide by precipitation; being formed at a sensible distance from the metal, this precipitate is naturally not protective, but may even help the anodic reaction by absorbing oxygen.

Action of N/10 zinc sulphate. Drops of zinc sulphate solution placed on steel produced no membrane, but a greyish-buff deposit appeared over the ground covered by the drops; there was distinctly more deposit round the edges of the drops than in the centre—in striking contrast to most other cases of drop-corrosion. Much of the deposit could be rubbed off with the fingers, but there remained an adherent layer, brownish-grey at the edges and gradually passing to purer grey in the centre. This was partly dissolved, partly loosened, by sodium hydroxide solution, and after treatment with that reagent, rubbing revealed the bright steel below.

The explanation of the action of zinc sulphate would appear to be as follows. The primary anodic product must be a soluble salt (ferrous sulphate), but the cathodic product will be sparingly soluble zinc hydroxide, which will appear mainly around the edges of the drop. In the outer part to which oxygen can penetrate most easily, zinc hydroxide may react with the ferrous sulphate, partially precipitating iron as ferric hydroxide, and thus the final insoluble product will contain both zinc and iron hydroxides.

Five drops of zinc sulphate solution placed on iron for 24 hours at 29° contained 0·17, 0·12, 0·17, 0·30, and 0·16 mg. of iron; three drops of distilled water acquired 1·0, 1·05, and 0·95 mg. in the same time. It would seem that the insoluble cathodic product (zinc hydroxide) prevents the access of oxygen to the outer part of the metallic surface, and thus retards corrosion, notwithstanding the

[10] Trans. Faraday Soc., 1922, 18, 1; 1923, 19, 789.
[11] Engineer, July 6, 1923.

fact that the anodic product is more soluble than in the case of distilled water.

Action of N/10 nickel sulphate. Nickel sulphate produces a similar effect to zinc sulphate, but the deposit—which is mainly to be seen around the edge and least in the centre—is rich brown instead of buff in colour; the deposit is much less closely adherent than in the case of zinc sulphate. Possibly for this reason the amount of iron taken up by the drop is greater than in the case of zinc sulphate; six drops after 24 hours at 29° contained 0·75, 0·55, 0·48, 0·55, 0·90, and 0·82 mg. of iron respectively.

Classification and summary.

The corrosion of iron or steel by a drop of aqueous liquid depends in most cases on electrochemical action between the central, unaerated area, which becomes anodic and suffers attack, and the peripheral, aerated portions, which become cathodic, and in general remain unattacked. The velocity of attack depends largely on whether the anodic and cathodic products are soluble or insoluble. In the case of pure water, the anodic product, ferrous hydroxide, is perceptibly soluble, and spreading outwards becomes oxidised at the junction between the aerated and unaerated regions, yielding a brown ring of the nearly insoluble ferric hydroxide, which extends over the top of the drop as a membrane. The action of salts (in N/10 concentration) may be classified as follows:—

(1) Salts like potassium chloride, potassium sulphate and potassium nitrate yield a soluble anodic product (ferrous chloride, sulphate, or nitrate) and a soluble cathodic product (potassium hydroxide), and increase the velocity of corrosion; where the ferrous salt and alkali mingle, a ring of ferrous hydroxide, oxidising to ferric hydroxide appears, and extends as a membrane over the surface. Outside the membrane the iron is unattacked, but the formation of alkali at the periphery (cathodic portion) causes spreading of the liquid.

(2) Salts like zinc sulphate yield a soluble anodic product, but an insoluble cathodic product (zinc hydroxide), which shields the cathodic area from diffusing oxygen, slightly diminishing the rate of corrosion.

(3) Salts like sodium carbonate, sodium phosphate, and potassium ferricyanide yield a soluble cathodic product and an insoluble anodic product, which forms a closely adherent protective skin, usually invisible, over the metal. In such cases corrosion is almost prevented; but occasionally at certain points, especially at the edge of the drop, the film fails to adhere, and at such points marked localised anodic corrosion occurs; this breakdown occurs quite quickly in more dilute solutions of sodium carbonate.

(4) Potassium chromate causes passivity even in the parts to which oxygen cannot diffuse; no differential-aeration currents are set up, and there is practically no corrosion. If, however, chlorides also are present in large quantity, the protective film breaks down at the edge, and serious localised corrosion will result; nitrates act more slowly than chlorides in causing the breakdown of the film, whilst sulphates are still less active in this respect.

OURNAL of THE SOCIETY OF CHEMICAL INDUSTRY

. XLIII., No. 45.] TRANSACTIONS [November 7, 1924.

IE VISCOSITY OF SYRUPY CONDENSATION PRODUCTS OF PHENOL AND FORMALDEHYDE.

BY ALAN A. DRUMMOND.

niformity in composition and properties of the hed material is an essential in the commercial luction of synthetic resins, especially such as are ined from the condensation of phenol and formhyde. Such uniformity can only be effected ystematic control of the manufacture from its l stages. Methods based on chemical analyses been indicated for application to the raw rials and the aqueous liquors involved (Ormandy Craven, J., 1923, 18T), but it is recognised that iderable difficulty exists in checking effectually constancy of composition and condition of the lensation products in their viscous syrupy form.

o deal with these syrups physical methods natur- suggest themselves. Attempts have been made ontrol the condensation by observations of the ge in density (Jablonower, J. Amer. Chem. Soc., 3, 35, 811), but beyond a certain point in the rse of the condensation density is of little use in ecting differences in the condition of the syrup. as, however, been shown generally (Batschinski others, see "Fluidity and Plasticity," Bingham) t the rate of change of viscosity is very much higher n that of density, and consequently viscosity ues offer a delicate means of control in factory ocesses, and particularly has this been found to be case in the manufacture of formaldehyde condenion products. It can be shown that in a series of ndensation syrups having practically identical sities, one syrup may have at least three times viscosity of another in the series.

It is the intention to indicate briefly here the thods which have been usefully employed in the asurement of the viscosity of condensation syrups, l to give certain figures obtained, and the deducns made therefrom as to the physical character condensation syrups.

Very little reference can be found in the literature the viscosity of condensation products of phenol l formaldehyde. Van Voorhout (Chem. Weekblad, 20, 17, 2) draws conclusions as to the condensing wer of various catalysts from a study of the visity of the reaction mixture, but does not quote y figures. R. S. Morrell (Third Report on Colloid emistry, 1920, p. 113) calls attention to the necesy for the study of physical constants in relation synthetic organic colloids such as the phenolic xymethylene resins, and states that viscosity, ation, relaxation effects, and dielectric properties await investigation.

Where accurate absolute values are required the ling sphere viscosimeter is of particular value bson and Jacobs, Chem. Soc. Trans., 1920, 117, 473) and was used in the investigation of these syrups, castor oil being employed as calibrating liquid.

The usual air-bubble viscosimeter of the varnish maker is not altogether satisfactory for general use, particularly where more viscous liquids are concerned, although in the hands of the experienced varnish foreman it serves as an excellent guide, is readily applied and is simple in construction. In this connexion, attention may be drawn to an improved factory viscosimeter used by E. I. du Pont de Nemours and Co., which has been described recently by Marasco (Ind. Eng. Chem., 1924, 16, 172), and is capable of development in many industries.

For fairly rapid comparative determinations of viscosity of factory products in the industrial condensation of phenol and formaldehyde, useful results have been obtained by the adaptation of a method originally described for use in controlling the preparation of insulating varnishes of low viscosity (Whalley, Analyst, 1919, 44, 288). It can, however, be applied to liquids of viscosity at least as high as that of golden syrup.

In this method the values obtained appear to have no simple relation to absolute viscosity. An attempt was made to establish a definite relationship between these values and absolute values obtainable by means of the falling sphere viscosimeter. Within certain limits of viscosity a smooth curve was arrived at, but beyond these limits the relation was uncertain. A rough working curve was, however, drawn from a large number of comparative determinations by the two methods. With this curve it was possible to obtain an approximate idea of the absolute viscosity from results obtained with the Whalley method.

In spite of the drawback stated, the method was useful in works control, and gave satisfactory and concordant figures in routine use. It consists in immersing a definite portion of a microscope slide in the liquid under examination, withdrawing the slide, and weighing the residue on the slide after drainage for a stated time. Precautions as to temperature and rate of withdrawal are taken. It was found more convenient in using this method to lower the viscosities of the syrup samples by the use of a diluent to bring them within the region of greater accuracy. Aqueous glycerol (70%) was found suitable for this purpose.

The viscosities of mixtures of condensation syrup with glycerol are shown in Table I. with the value for castor oil added for comparison.

TABLE I.

Composition of sample (Parts by wt.) Condensation syrup.	70% Glycerol.	Viscosity at 25° C. Poises.
100	0	112
80	20	10·5
75	25	5·6
70	30	3·6
60	40	2·0
Castor oil	..	6·5

It is more satisfactory, in viscosity work, for the viscosities determined to be nearly the same as

that of the fluid used for calibrating the instrument, which was castor oil in this case. Now the value obtained with an addition of 25% of aqueous glycerol approximated to the viscosity of castor oil (see Table I.), so that this addition was standardised for all routine determinations of viscosity.

The viscosity-temperature relation and its bearing on colloidal character.

A study of the change of viscosity with temperature is of considerable value in certain industries, particularly that of oil, and where lubricating oils are concerned. The various empirical formulæ connecting viscosity and temperature have been thoroughly investigated in this connexion (Herschel, J. Ind. Eng. Chem., 1922, **14**, 715; Fortsch and Wilson, *ibid.*, 1924, **16**, 789). Bingham and his co-workers have given the question close attention in their study of fluidity.

It is frequently found that the expression of viscosity as its reciprocal (namely, "fluidity"), helps to a more simple elucidation of relationships. Thus, the relation between fluidity and temperature of many chemical individuals appears an almost linear one, particularly at high temperatures (Bingham, 'Fluidity and Plasticity," 1922, p. 133). Again, in connexion with the viscosity of oils, Oelschlager (Z. Ver. deut. Ing., 1918, **62**, 422) and Herschel (*loc. cit.*) have pointed out the value of the logarithmic diagram in ascertaining viscosities at different temperatures. Herschel has shown that the result of plotting the logarithm of the viscosity against the logarithm of the temperature in degrees Fahrenheit is practically a straight line with a large number of oils, and also with a number of other substances both aqueous and non-aqueous.

The viscosity-temperature relationship in these cases is in accordance with the mathematical expression due to Slotte (Beibl. Ann. Physik, 1892, **16**, 182), $\eta = c/(a+t)^n$: when a is zero the equation becomes $\eta = c/t^n$ (Herschel, *loc. cit.*, p. 717), which represents a straight line on a logarithmic diagram.

Herschel discusses the application of such straight line diagrams to the viscosity of oils and points out the significance of using the Fahrenheit scale for expressing the temperature instead of Centigrade in that it can be shown to be equivalent to using the correct value of a in the foregoing equation.

Logarithmic diagrams of this nature reveal abnormal conditions in certain materials by departure from the normal linearity. A connexion has been traced between such abnormality and the presence of colloidal material in the substance under examination (Herschel, *loc. cit.*). For instance, a sample of Mexican fuel oil showed strong curvature on such a diagram, and the sample gave evidence of marked viscosity hysteresis, a phenomenon attributed by Dunstan and Thole (J. Inst. Petrol. Tech., 1917-18, **4**, 201) to the presence of colloids. Again, Fortsch and Wilson (*loc. cit.*) have shown the same tendency to curved lines in the above relationship in the case of heavy petroleum residues, and also "road oil" from pressure tar, materials which might be suspected to contain colloids (see Fig. 1).

The possibility of colloidal character being [i]cated by the form of the logarithmic viscos[ity-]temperature graph is of sufficient interest to exa[mine] further with other classes of material.

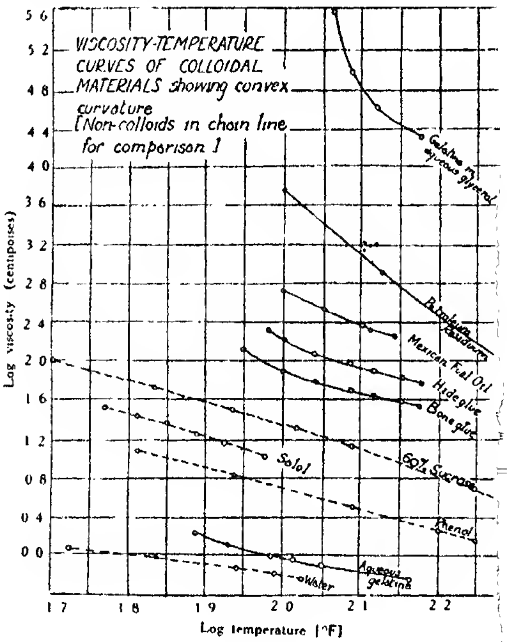


FIG. 1.

Seaton, Probeck, and Sawyer (J. Ind. Eng. Che[m.,] 1917, 9, 35) have associated the viscosity-temperat[ure] relationship with colloidal character in the case [of] varnishes. The shape of the curve varies accord[ing] to the presence or absence of highly polymerised oi[l.] Their observations are to be received with cauti[on] (H. H. Morgan, Ann. Repts., 1921, p. 339), si[nce] the type of viscosimeter used (Doolittle torsion) do[es] not lend itself readily to the presentation of absol[ute] values. It was, however, thought to be of interest [to] calculate some of their values on the logarithmic ba[sis] described, assuming that the Doolittle degrees [of] retardation, in which their viscosities are expresse[d,] are directly proportional to absolute viscosities, [an] assumption which is perhaps approximately true [for] the more viscous varnishes they examined are co[n]sidered in the re-calculation of the linear relatio[n]ship on the MacMichael torsion instrument, whi[ch] was true only above a certain minimum viscosit[y] where turbulence and centrifugal forces becar[ne] negligible (Herschel, J. Ind. Eng. Chem., 1920, 1[2,] 282).

It is interesting to find that the curves plotted fro[m] the figures thus obtained are in line with the observ[a]tions made with oils. A varnish containing a highl[y] polymerised oil and considered to be colloidal (showi[ng] Tyndall effect) is represented on the logarithm[ic] diagram by a well-curved line, whilst the same varnis[h] thinned down somewhat with acid linseed oil, an[d] thus presumably sufficiently dispersing the colloid t[o]

m a molecular or true solution, is represented by a aight line between 20° and 50° C. (see Fig. 2).

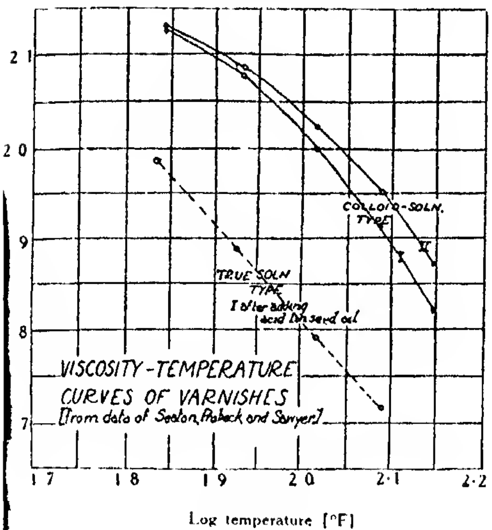

FIG. 2.

elatins and glues are of acknowledged colloidal acter. Bogue ("Gelatine and Glue," 1922, 189) studied the viscosity-temperature variation of se materials, and his values plotted as loga- ms reveal a definite curvature, both with bone hide glue. Curvature is also found with solutions elatin in water (calculated from the data of Davis Oakes; J. Amer. Chem. Soc., 1922, 44, 477), in aqueous glycerol (calculated from data of sz; Kolloidchem. Beih., 1915, 7, 1). It should be d that the curvature observed is convex to the rithmic temperature axis as distinct from the avity with pure water and ordinary aqueous tions (see Fig. 1).

ttention has been called to the foregoing general siderations with a view to their particular applica- to the problem of the physical condition of the lensation products of phenol and formaldehyde. ves connecting temperature and viscosity of con- sation syrup have been constructed by three hods: (1) where the viscosities are expressed in olute units; (2) where the viscosities are expressed heir reciprocals (fluidities); (3) where the loga- ms of the viscosities are plotted against the rithms of the temperatures in degrees Fahrenheit. shapes of the curves (see Fig. 3, Table II.) are as ws:—

) The viscosity-temperature (Centigrade or Fah- eit scale) graph is hyperbolic in form, flattening considerably at temperatures below about 15° C.

) The fluidity-temperature graph is definitely ed at low fluidities (high viscosities), becoming nptotic to the temperature axis, an effect to be ed with most liquids (water, alcohols, mineral fatty oils, etc.). At temperatures above about . a rapid fall in viscosity takes place with small ases in temperature.

(3) The logarithmic viscosity-temperature graph is practically a straight line when the temperature scale is Fahrenheit, and for a minimum range of 15° to 50° C., and its steep slope is only approached by substances like heavy oils. Calculation of the numerical relation between viscosity and temperature of condensation syrup from phenol and formaldehyde (basic catalyst) on the basis of the linearity of the logarithmic curve leads to the formula:—

$$\eta = 453 \times 10^{11} / t_f^{5 \cdot 2}$$

where η is the absolute viscosity measured in cen- tipoises and t_f is the temperature in degrees Fahren- heit.

TABLE II.

Temperature. °F.		Viscosity. Poises.		Fluidity (1/Viscosity in poises).
15	..	240		0.42
23	..	90	..	1.11
27.5	..	50	..	2.00
35	..	20	.	5.00
50	..	6	..	16.67

In the earlier general discussion the possibility of deductions from the form of the logarithmic curve as to colloidal character was shown. On these grounds, and in view of the facts mentioned in the fore- going paragraph, it would appear that syrups in the early stages of condensation of phenol and formalde- hyde (such as have been dealt with in the present work) contain no appreciable amount of colloidal matter.

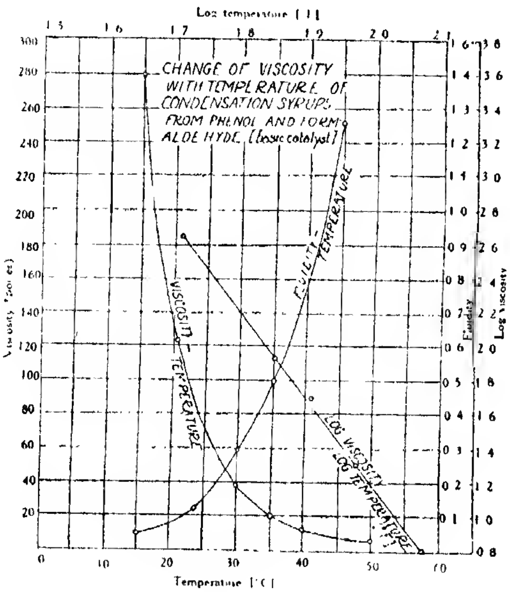

FIG. 3.

Physical character of condensation products in both syrupy and resinous condition.

In considering the physical and colloidal charac- teristics of the complete range of condensation pro- ducts of phenol and formaldehyde it is well to deal separately with (1) the initial syrupy product; (2) the intermediate soluble fusible solid resin; and (3)

the final infusible and insoluble resin. The data supplied in the work described above apply to the initial syrupy product.

One of the first products of the condensation is hydroxybenzyl alcohol. Van Voorhout (*loc. cit.*) was able to separate and identify *o*- and *p*-hydroxybenzyl alcohols from the product condensed with basic catalysts. Moreover, amongst the products of an acid condensation the same worker was able to identify dihydroxydiphenylmethane. Both Raschig and Baekeland have shown that *o*- and *p*-hydroxybenzyl alcohols are susceptible to polymerisation under the action of catalysts, giving first fusible soluble resins and finally resins which are softened by heat but do not melt, and are only slightly affected by solvents. In the light of Van Voorhout's work it may be supposed that this reaction consists in the condensation of the hydroxybenzyl alcohols to form dihydroxydiphenylmethane. Continued heating brings about polymerisation (Baekeland, J. Ind. Eng. Chem., 1909, 1, 159) which probably takes place simultaneously with the later stages of condensation (Jablonower, *loc. cit.*), the physical state gradually passing from the mobile condition of the fused hydroxybenzyl alcohols to a viscous syrupy mixture with ultimate formation of a slightly plastic resin hardly affected by solvents. The final resin would, following the conclusions of Van Voorhout, consist of polymerised dihydroxydiphenylmethane in solid solution in the normal dihydroxydiphenylmethane. In fact, it would then be comparable with the resinous or glassy forms of substances belonging to the group of iso-colloids, such as phosphoric acid or styrene, which in arriving at their solid forms pass through stages, gradually increasing in viscosity, of colloidal solution of the solid form in the liquid, both forms being of the same chemical constitution (Ostwald, "Colloid Chemistry," 1919, p. 104).

This picture might be considered to represent the stages of formation of the commercial hard, infusible and insoluble resin, such as transparent Bakelite, which frequently contains in addition residues of free phenol (Herzog, Z. angew. Chem, 1921, 34, 97).

As far as the initial syrups are concerned, from the conclusions summarised above and from the viscosity-temperature relationship, a working conception of their nature may be further developed. They may be looked upon as consisting of a combination of the following crystalline solid substances in a state of ordinary molecular solution :—*o*-hydroxybenzyl alcohol, m.p. 82° ; *p*-hydroxybenzyl alcohol, m.p. 110° ; dihydroxydiphenylmethane, m.p. 158° phenol (see Ormandy and Craven), m.p. 42·5°, including a small percentage of aqueous and uncombined formaldehyde. The mutual influence of each tends to lower the solidifying point and, owing to the rapid rise in viscosity as the temperature is decreased, crystallisation is permanently retarded. The retarding influence of viscosity on the rate of crystallisation has been studied in the case of liquids cooled below their solidifying point, such as salol (Wilson, Phil. Mag., 1900, 50, 238). The linear rate of crystallisation of salol measured in long glass tubes is found to be of the order of 1 mm. per minute, the viscosity of undercooled salol* at ordinary temperature being about 36 poises (see Fig. 1). The viscosity of the initial condensation syrup from phenol and formaldehyde (basic catalyst) at ordinary temperature is about four times this value.

The presence of foreign matter is also known to depress the rate of crystallisation of a substance and this is attributed to adsorption. Freundlich ("Kapillarchemie," 1922, p. 449) states that the lowering of the rate of crystallisation by impurities depends on the amount of impurities adsorbed by the crystals that are endeavouring to form. This effect is undoubtedly contributory to the non-crystallisation of condensation syrups.

Summary.

(1) The applications of viscosity determinations to the manufacture of condensation products of formaldehyde, are discussed.

(2) The relation between viscosity and temperature of the initial syrupy condensation product of phenol and formaldehyde, made with basic catalysts, is shown to be a linear one when logarithmic values are taken, and capable of expression by a simplification of Slotte's formula $\eta = K/t^n$, where t is in degrees Fahrenheit.

(3) The interpretation of viscosity-temperature relations in its bearing on colloidal character is applied to condensation syrups, and appears to indicate freedom from colloids while in the initial syrupy condition.

(4) The colloidal character of the resinous product is discussed.

* It may be noted that the logarithmic viscosity-temperature relations with undercooled salol is a linear one (see Fig. 1), which is of interest in relation to condensation syrups regarded as undercooled liquids, which, as has been stated, also show linearity in this relationship.

THE PREPARATION OF CYANOACETIC ESTER (ETHYL CYANOACETATE).

BY OSWALD C. STEPHENS, M.SC.

(*Concluded from p.* 314 T.)

Alternative methods for preparation of cyanoacetic ester.

/ the action of potassium cyanide in aqueous :ion on potassium chloroacetate an almost ititative yield of cyanoacetic acid can be obtained. separation of the cyanoacetic acid is, however, laborious, necessitating repeated crystallisations alcohol. There did not seem any valid objec- to esterifying the cyanoacetic acid directly out separation. According to Phelps and Tillot- (Amer. J. Sci., 1908, **26**, 243) the use of hydro- ic acid as a catalyst in the esterification caused formation of malonic ester, whilst no hydrolysis very little) occurs when sulphuric acid is used. seemed very improbable, so determinations were ed out on the esterification of cyanoacetic acid, on the rate of hydrolysis of cyanoacetic ester acid using alcoholic hydrochloric acid.

terification of cyanoacetic acid.—The esterification ed out according to Phelps and Tillotsen (*loc. cit.*) te an 85% yield.

Esterification of cyanoacetic acid using alcoholic rochloric acid.—50 g. of cyanoacetic acid were erified with 2 g. of hydrochloric acid in 200 c.c. of solute alcohol. By titrating 1 c.c. with baryta intervals the course of the esterification was lowed. The esterification was finished in one ur. 44 g. (65%) of cyanoacetic ester and 8 g. of lonic ester were obtained. An esterification using g. of hydrochloric acid to 50 g. of cyanoacetic acid is carried out in the same manner, and 1 c.c. rated with $N/4$ baryta. Using half the quantity of drochloric acid, the reaction took two hours to ich equilibrium. The contents of the flask were en heated on a water-bath under slightly reduced ssure until no further distillate was obtained. iother 200 c.c. of absolute alcohol, containing 1 g. hydrochloric acid, were added, and the mixture was luxed one hour. The titration then required 0·8 c.c. $N/4$ baryta, corresponding approximately to the ydrochloric acid taken. The product was distilled *in vacuo* to avoid volatilisation of the small amount of ammonium chloride formed by hydrolysis of the cyanoacetic acid. 46 g. of cyanoacetic ester were obtained (75%) and 8 g. of malonic ester.

In order to test the effect of the hydrochloric acid on the cyanoacetic ester, 10 g. of cyanoacetic ester in 20 c.c. of absolute alcohol with 0·2 g. of hydrochloric acid were boiled on the water-bath under a reflux condenser and 1 c.c. was removed at intervals and titrated with $N/20$ baryta, the hydrolysis of the ester being shown by the decrease in acidity due to hydrochloric acid forming ammonium chloride.

Time in minutes	0	5	20	60	120	180	300	360
Titration ..	6·1	6·1	5·9	5·55	4·9	4·9	3·7	3 c.c.

Thus the hydrolysis of cyanoacetic ester to malonic ester under these conditions is practically negligible.

The ordinary laboratory preparation of malonic ester is carried out in the presence of a large excess of sulphuric acid. It is not practicable to esterify the sodium cyanoacetate by means of alcohol and sulphuric acid without, at the same time, hydrolysing and esterifying the cyanogen group; for it is impossible to control the addition of sulphuric acid just sufficient for the esterification, owing to the formation of acid salts or acid esters. There is not the same difficulty with hydrochloric acid: and, considering the results just recorded, it seemed possible by the use of hydrochloric acid to secure a satisfactory esterification of the cyanoacetic acid without previous separation from the salt. 50 g. of chloroacetic acid were converted into sodium cyanoacetate in the usual way. The aqueous solution of the cyanoacetate was then evaporated to dryness, with constant stirring, and heated until the temperature reached 135°, the mass was allowed to cool in a desiccator and, when cool, rapidly broken up into lumps, and covered with absolute alcohol. Then just sufficient alcoholic hydrochloric acid was added to set free the cyanoacetic acid and leave 2 g. excess to act as a catalyst in the esterification. 25 g. of hydrochloric acid were needed. This was added in 186 c.c. of alcohol. When the mixture boiled, hydrogen chloride was given off, so a further 100 c.c. of absolute alcohol were added. The course of the reaction was followed by withdrawing 1 c.c. at intervals and titrating with $N/4$ baryta. 24 g. of cyanoacetic ester and 9 g. of malonic ester were obtained. Thus the yield was 40% calculated on the chloroacetic acid taken.

Comparing this yield with that obtained by first esterifying chloroacetic acid by the Fisher–Speier method and subsequent conversion of the chloroacetic ester into cyanoacetic ester, we find that the esterification gives a 77% yield and the conversion into cyanoacetic ester a 60% yield. Thus the yield over the whole process is $77 \times 60 \div 100 = 46\%$.

The fact that hydrogen chloride is given off would indicate a slow reaction between the sodium cyanoacetate and the hydrochloric acid, thus explaining the large amount of malonic ester formed, as the cyanoacetic acid first set free is, to a large extent, hydrolysed to malonic ester. To obviate this, after evaporation of the solution of sodium cyanoacetate to dryness, the fused mass is broken into lumps (it is too deliquescent to be ground into a mortar), rapidly placed in a round-bottomed flask, and covered with absolute alcohol. This is then boiled for 30

minutes on the water-bath to secure a partial disintegration, cooled, the calculated amount of hydrochloric acid added, and the mixture allowed to stand for 12 hours. It is then heated on the water-bath to esterify the acid in the usual way. As in the last experiment, the course of the esterification was followed by titrating 1 c.c. of the mixture against $N/4$ baryta. 36 g. of cyanoacetic ester and 11 g. of malonic ester were obtained (yield 63%).

Further experiments have given most conflicting results, and varying yields of 20%, 42%, and 60% have been obtained. The reaction seems very sensitive to conditions. A certain amount of hydrolysis does occur in the evaporation of the aqueous solution of cyanoacetate, but with careful control an average yield of 50% should be obtainable.

Summary.

1. By the preparation of cyanoacetic acid from chloroacetic acid in aqueous solution, separation of the cyanoacetic acid, and subsequent esterification, a yield of 85% is obtained. This entails the laborious separation of cyanoacetic acid.

2. By the preparation of chloroacetic ester from trichloroethylene and its conversion into cyanoacetic ester in alcoholic solution, a yield of 48% is obtained. The cheapness of trichloroethylene and the relative simplicity of the method may render it more economical than 1.

3. Esterifying the chloroacetic acid and then transforming the chloroacetic ester into cyanoacetic ester in aqueous alcohol, gives a yield of 35%.

4. Preparing cyanoacetic acid from chloroacetic acid in aqueous solution and then esterifying the cyanoacetic acid without separation may give a yield up to 60%. In addition to this, malonic ester is formed as a valuable by-product.

The author desires to express his thanks to Dr. J. K. H. Inglis, of Otago University, for his unfailing assistance and helpful suggestions throughout the course of this research.

'HE DESIGN AND OPERATION OF GAS SCRUBBING TOWERS.

BY H. D. H. DRANE.

l'he problem of the design of gas scrubbing towers in general exceedingly complicated, because of ; many variable factors affecting the rate of ition of the constituent to be dissolved; and an ;t experimental study of the operation with the ct of obtaining design data is rendered difficult use of the cumbersome analytical expressions ssary. It is, however, possible by proper choice, udy the operation of a gas scrubbing tower under specified conditions, where the number of ables is reduced to a minimum, and under exact rol, thus permitting the study of these controlled ables.

urter[1] in 1885 to 1893 carried out much in- lative experimental work, and summarised y of the important factors governing the various s of scrubber in use. More recent contributors paid due regard to specific properties of the solvent, and packing, and have deduced relation- which are capable of experimental study r certain specified conditions. Thus, Lewis[2] leveloped very fully the theory of counter-current scrubbing towers and analogous apparatus, ıg general relationships which are applicable such processes as heat transfer, leaching, and absorption. More recently, Partington and ker[3] have successfully dealt with the specific blem of the absorption of nitrous gases by dilute ric acid, in which special considerations arise. nnan and Masson[4] have dealt analytically with process of gas scrubbing in general, making t several necessary simplifying assumptions.

'he factors affecting the operation of a gas ubbing tower may be summarised:—

a) Solubility relationships of gas and scrubbing iid.

b) Scrubbing surface, nature and extent.

c) Rates of liquid and gas flow.

d) Special considerations: (i.) Temperature nges, (ii.) formation of compounds, (iii.) viscosity,

n a preliminary study it is desirable to reduce se factors to the three first mentioned, in which the operation may be analytically expressed ply. In the present paper, attention is cted to the operation of a tower under the lowing conditions: (*a*) Counter-current flow; (*b*) nstant flow rates; (*c*) absorbable constituent eys Henry's law; (*d*) process is isothermal. This the case treated by Donnan and Masson.

Assuming that the process of solution of the luble gas is governed by the law[5]

$$dx/dt = SK_2(KM - N) \qquad \text{(i.)}$$

[1] Hurter, J., 1885, 639; 1887, 607; 1893, 227, 989.
[2] Lewis, J. Ind. Eng. Chem., 1916, 8, 825.
[3] Partington and Parker, J., 1919, 75T.
[4] Donnan and Masson, J., 1920, 236T.
[5] Adeney and Becker, Proc. Roy. Dub. Soc., 1918, 15 (N.S.), 385, 609.

where K_2 = dissolution coefficient of the gas defined from the above equation, K = Henry coefficient, S = surface of solvent, M = concentration of absorbable gas in gas phase, N = concentration of absorbable gas in liquid phase, x = weight of dissolved gas.

And writing in an actual scrubbing tower:— M_1 = concentration of absorbable constituent X in gas phase at entry (in grams per litre), M_2 = ditto at exit, m = ditto at a section of the tower AA, N_1 = concentration of X in liquid phase at entry (in grams per litre), N_2 = ditto at exit, n = ditto at a section of the tower AA, h = total length of packing in tower (in metres), x = distance (in metres) of AA from entry of liquid. V_g = flow of gas in litres per minute, V_l = flow of liquid in litres per minute, S = area of cross-section of tower, K = absorption coefficient of X in the scrubbing liquid defined by the ratio at equilibrium (grams X per litre liquid/ditto gas), K_1 = square metres of wetted surface per cubic metre of tower. K_2 = dissolution coefficient of X (expressed as grams per square metre per minute).

$$V_g/V_l = f$$

By application of equation (i) to the process occurring in a small horizontal section of the tower at AA of thickness dx:—

$$V_g.dm = V_l.dn = K_1K_2S(Km - n).dx \qquad \text{(ii.)}$$

From these relationships Donnan and Masson were able to write:—

$$\log_e \frac{(K-f)n + K(fM_2 - N_1)}{f(KM_2 - N_1)} = \frac{K_1K_2S}{V_g}(K-f)x \qquad \text{(iii.)}$$

$$\log_e \frac{(K-f)m + (fM_2 - N_1)}{KM_2 - N_1} = \frac{K_1K_2S}{V_g}(K-f)x \qquad \text{(iv.)}$$

If N_1 is zero (*i.e.*, pure solvent enters the scrubbing tower) these equations simplify; thus equation (iii.) becomes:—

$$\log_e \left(1 + \frac{K-f}{KfM_2}n\right) = \frac{K_1K_2S}{V_g}(K-f)x \qquad \text{(v.)}$$

In these relationships the working of a gas scrubbing tower is characterised by the two coefficients K_1 and K_2; and by inspection it is possible to see the type of experiment required to enquire into their nature and value. In the foregoing relationships, as also in any others which may be deduced relating to the operation of a tower, the coefficients K_1 and K_2 occur in product form, and consequently any separation will be arbitrary. In making such a separation, it is helpful to regard K_1 as invariant and equal to the simple geometric surface of the packing used, treating any variation in the product as due to a change in K_2, *i.e.*, a change (or an apparent change) in the rate of solution of the gas.

Equations iii. and iv. give relationships capable of experimental examination between x (the distance traversed by the gas and liquid through the tower) and m and n (the concentrations of dissolved gas, in the gas and liquid phases, respectively, at the point x), in terms of K_1, K_2, and factors such as K, f, and M_2,

which may also be determined experimentally. The method of enquiry into the nature and value of K_1 and K_2 is thus to study the variation of gas and liquid concentration throughout a tower, under known conditions of flow and packing, etc. Such a study was desirable as a preliminary step in the classification of various types of commercial packing and of types of scrubbers (plate columns etc.), and the investigation described herewith was undertaken.

To study the process upon a scale corresponding to that likely to be met in actual practice, an experimental tower was used as shown in Fig. 1, which allowed the use of commercial packings. The use of a comparatively large apparatus was considered essential, in view of the misleading results likely to be obtained by experiments with small apparatus, though these latter might conceivably be exact small-scale models. The packing used in the tower (4-in. "propeller" tower filling) was such as to afford a surface, the area of which could be computed and was arranged uniformly, in view of the purpose to which the tower was to be put. As a gas supply a mixture of air and carbon dioxide (up to 12% CO_2) was used, since the solubility relationships of carbon dioxide are well established[6] and known to be according to Henry's law and the law of dynamic solution expressed by equation (i.) (*supra*). Moreover, under the conditions of experiment the process of solution was practically isothermal, no detectable temperature variations due to solution of the gas being observed. In order to avoid any undesirable temperature changes in the body of the tower due to evaporation, a preliminary saturating tower as shown in Fig. 1 was incorporated in the apparatus, and was supplied with an excess of water of the same temperature as that used in the tower, the spray being carried forward and deposited in the compartments of the mixing box where the carbon dioxide was introduced. The arrangements for metering the streams of air and carbon dioxide are shown, these being by means of two Kent orifice meters reading accurately to 0·5%. It was found necessary to introduce loaded, water sealed gasometers in the carbon dioxide main in order to maintain a steady pressure, the supply being unsatisfactory when taken directly from a battery of cylinders. Facilities were provided for the insta

ous removal of samples of gas and liquid at vals of their progress through the tower by the ratus shown in Fig. 2. In an actual experiment, was necessary to assure that steady conditions ined throughout the tower. To this end, the r was first supplied to the tower for some time, der to attain a uniform temperature throughout, e adjusting the flow to the particular rate desired. gas and air supplies were then also adjusted and apparatus was allowed to run until the issuing concentration became constant, as shown by the val and analysis of successive samples. At this samples of gas and liquid were removed for sis from each orifice fitted to the tower, and also issuing and entering gas and liquid. These ses were performed: (*a*) for the gas, directly easurement of volume contraction on treatment caustic potash; (*b*) for the liquid, by measure- of the contraction obtained on treatment with appreciable quantities of dissolved carbonates, and these values, slightly lower than those applying to air-free distilled water, were used throughout in the calculation of results. From the results of the analyses of the gas and liquid samples, the curves giving m and n as functions of x were first constructed, and from these one of the derived expressions such as $\log_e [1+n(K-f)/KfM_2]$ was plotted as a function of x. The derived curve indicated was found in all cases to approximate to a straight line, thereby confirming the applicability of the relationships used. From its gradient the values of the coefficient K_2, were obtained, which are shown attached.

The temperature throughout an individual experiment was constant. Range of temperature of above experiments, 7°—10·5°C. No temperature corrections have been applied.

It will be seen that the value of K_2 is not influenced greatly by change in liquid flow rate, but increases

[7] This was found to be the only satisfactory method applicable to these alyses. Titration or precipitation methods gave extremely inaccurate sults when applied to the determination of carbon dioxide in solution. Many of these inaccuracies are ably reviewed and criticised in a paper by Johnstone (J. Amer. Chem. Soc., 1916, 38, 947).

rapidly with increase in gas flow rate over the range studied. The variation may be expressed approximately by:—

$$K_2 = 2{\cdot}43\,L_g\overline{K}_2 - 1{\cdot}0 \qquad \text{(vi)}$$

Where L_g denotes the linear velocity of the gas through the packed tower (metres/minute) and $\overline{K}_2$ denotes a specific value of K_2 ($\overline{K}_2 = 1{\cdot}15$: see further below).

The rapid increase of K_2 with increase in gas-flow rate is considered due to a turbulence effect (*cf.* heat transfer coefficients, pipe resistances, etc.), which hastens the removal of impoverished gas from the liquid surfaces. The fact that no consistent variation was observed in K_2 as due to variation in liquid flow, indicates that over the range examined the packed surface was completely wetted, and that increase in liquid-flow rate mainly increased the thickness of the film of water trickling over the packing. It is probable that an increased surface will be afforded at still higher rates of liquid flow (increase in scrubbing surface would appear as an increase in K_2) due to splash and drip effects, but because of experimental limitations this could not be tried. A more exact relationship will probably give K_2 as some power function of the gas velocity and a value of K_2 under certain specified conditions. Clearly, the most

readily realisable conditions under which a value of K_2 can be specified and experimentally determined on a small scale, are those of zero gas velocity—*i.e.*, the simple efflux rate of gas from a solution into an atmosphere free of the dissolved gas. Determination of this limiting value of K_2 for any particular gas, permits by means of equation (vi.), the calculation of the value of K_2 at any specified gas-flow rate which applies in the design of a tower to effect absorption at that flow rate.

To test the validity of the suggestion outlined above, experiments were carried out to determine the value of K_2 for carbon dioxide with respect to the water used in the tower, by a small-scale method, and the values so obtained were compared with those obtained in working with the tower at low-gas velocities.

K_2 = velocity constant of solution, K_3 = velocit constant of loss of gas.

1. Loss of gas to atmosphere

$$dx/dt = -K_3Sx/V$$
$$K_3 = V/St. \log_e(x_0/x_t) \qquad \text{(vii.)}$$

where K_3 is a coefficient governing rate of loss.

The process of solution from an atmosphere co taining M grams per litre, however, procee according to :—

$$dx/dt = SK_2(KM - x/V)$$

which may be written separately

$$dx/dt = KK_2SM - K_2Sx/V$$

showing the dynamic nature of the process, in w the constant K_3 evidently is identical with K_2.

MIXING BOX

FIG. 3.

Consider a solution containing dissolved gas exposed to an atmosphere free of the dissolved gas: Let S = surface in sq. m, x = weight dissolved in grams, V = volume in litres, t = time in minutes,

The method of experiment used was to take water solution of carbon dioxide (about 1500 c.c in a glass vessel of circular horizontal cross-secti (115 sq. cm.), the liquid reaching to the lip of the vess

vas found necessary to screen the surface of the tion from any direct draught, otherwise the s of K_2 determined did not approach constancy. ng of the solution was effected at such a rate the surface remained unbroken and approxi-ely horizontal. Provided that these conditions observed, consistent results were readily ined, the rate of stirring being capable of varia-over a considerable range with little influence . Samples of the solution were run off for s, without disturbing the surface or stirring, inute intervals and the values of K_2 determined m equation (vii.) above, with the following :—

Temp. °C.	8·7	10·2	10·2	11·7	14·5.
K_2	0·97	1·15	1·03	1·13	1·22.

to be noted that (1) the temperature coefficient ll and insufficient to justify corrections on ount to values of K_2 obtained in working with er; (2) the value is of the same order as that ined in experiments with the tower at low f gas flow.

Hence

$$\int_0^h (Km-n).dx=(KM_2-N_1)\ (e^{ph}-1)/p$$

$$=h\ \frac{(K-f)\ M_1+f\ (M_2-N_1)-(KM_2-N_1)}{\log_e [(K-f)\ M_1+f(M_2-N_1)]/(KM_2-N_1)}$$

Hence $W=K_1K_2Sh\ \dfrac{(KM_1-N_2)-(KM_2-N_1)}{\log_e (KM_1-N_2)/(KM_2-N_1)}$ (ix.).

This relationship is strictly similar to that applying to the process of heat transfer, and an application is indicated in the problem given below. In applying the experimental data it is not possible to discuss the effect of different packings, and the data are applicable strictly only within the range studied (*i.e.*, to a linear gas velocity of 3 metres per minute). It is justifiable, however, to apply the results to the consideration of towers of different dimensions, but retaining the same packing and corresponding flows of gas and liquid.

Problem.—A supply of gas 5000 litres per minute containing 0·1 g. per litre of a soluble gas having a Henry coefficient of 1·3 expressed as g.p.l. liq./

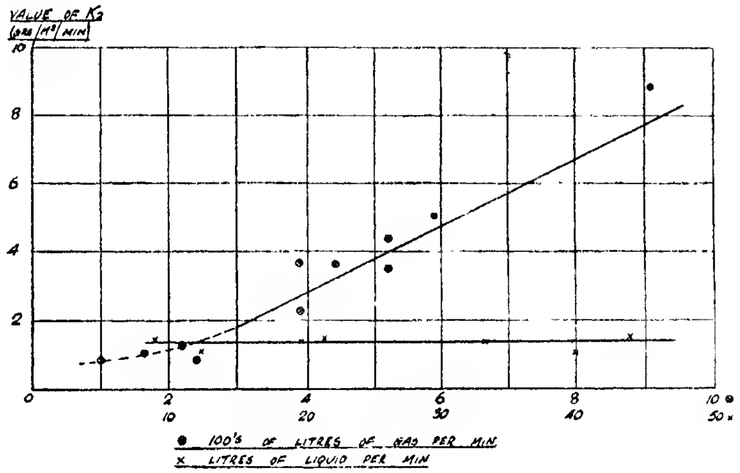

FIG. 4.

proceeding to apply values of dissolution co-nts in the design of a tower, it is desirable to relationships more convenient in their application the differential relationships used in the earlier on of this paper.[8]

ing the previous notation: For the material fer per minute:—

$$dW=K_1K_2S(Km-n)dx.$$

$$W=K_1K_2S\int_0^h (Km-n)\ dx. \qquad \text{(viii.)}$$

From equations (iii.) and (iv.) and writing

$$(K-f)\ K_1K_2S/V_g=p,$$

$$m-n)=\frac{K}{K-f}\ (KM_2-N_1)e^{px}-\frac{f}{K-f}(KM_2-N_1)e$$

$$=(KM_2-N_1)e^{px}$$

g.p.l. gas at equilibrium, is to be scrubbed to a concentration of 0·08 g.p.l. Its dissolution co-efficient determined statically is 1 (gram, litre, sq. m. minute units). Efficiency of scrubbing required =80%.* To determine suitable dimensions for a scrubbing tower.

Gas exchange per minute=5000×0·02 g.=100 g.

At 80% efficiency, issuing liquid concentration =0·104 g. per litre, and very approximately 1000 litres per minute of solvent are required. Applying equation (ix.)

$$100=\text{surface}\times K_2\times(-0{\cdot}078)/\log_e\ [0{\cdot}026/0{\cdot}104]$$

If the gas velocity, through the packed tower is kept above 2 metres per minute, K_2 may be taken as 3. Hence the required surface is 600 sq. m.

Using a packing affording 90 sq. m. per cub. m. packed, the packed volume required =6·7 cub. m.

[8] The logarithmic relationship given was published (J. Ind. Eng. Chem., 12, 115) by Van Arsdel during the progress of this work and was also d ind endently. See also Lewis, *loc. cit.*

*Efficiency of scrubbing $=\dfrac{\text{g.p.l. leaving liquid}}{\text{g.p.l. entering gas}}\div K.$

Suitable dimensions for the tower are: Height, 7 metres; diameter, 1·1 metres.

Summary.—The operation of gas scrubbing towers is considered from the standpoint of the influence of rate of gas and liquid flow upon the dissolution coefficient of the gas to be extracted.

An experimental study of tower operation with carbon dioxide is described. The results show that the dissolution coefficient is independent of liquid flow rate over the packing, but increases rapidly with increase in gas flow rate.

A relationship analogous to that applying to heat interchange is given and applied to the design of a tower.

In conclusion the author wishes to thank Prof. F. G. Donnan for his interest and suggestive criticism during the progress of the work described.

THE RECIPROCAL SALT-PAIR $Na_2Cr_2O_7 + 2KCl \rightleftarrows K_2Cr_2O_7 + 2NaCl$.

BY JOHN B. ROBERTSON, M.A., B.SC., A.I.C.

Since one of the processes used for the manufacture of potassium bichromate depends upon the double decomposition of sodium bichromate with potassium chloride and subsequent crystallisation of the potassium bichromate formed either spontaneously or by evaporation, the determination of the phase-rule equilibria existing in the above system has a certain importance.

A series of determinations has been made by the author of the composition of solutions which are in equilibrium with one, two, or three of the salts of the system existing as solid phases. This involves a survey of the following:—

Three-component systems: $KCl—K_2Cr_2O_7—H_2O$; $NaCl—Na_2Cr_2O_7—H_2O$; $KCl—NaCl—H_2O$, and $K_2Cr_2O_7—Na_2Cr_2O_7—H_2O$. Four-component system: $(K, Na)—(Cl, Cr_2O_7)—H_2O$.

The system $KCl—NaCl—H_2O$ has already been investigated by Reinders (Z. anorg. chem., 1915, **93**, 202). Data for the other systems are here given. Three isotherms have been constructed, namely at 25°, 50°, and 100°. In order to obtain the solutions for analysis, mixtures of the pure salts were dissolved in water at a higher temperature than that of the isotherm and the flasks containing these solutions then immersed in thermostats. Equilibrium was reached in a few hours, but generally the solutions were allowed to remain at constant temperature for at least twelve hours before sampling. The nature of the solid phase or phases separating out could usually be determined by inspection, the distinctive colours and crystalline forms of the salts rendering this possible, but in every case invariant points were checked by at least two analyses, the second being made after further addition of one of the solid phases or after considerably evaporating the solution. The solutions were sampled by rapidly sucking up a portion through a plug of cotton wool into a piece of glass tubing and decanting t clear liquid obtained into a tared weighing bot After weighing, the whole was made up to defin volume in a graduated flask and the various radic were determined in aliquot parts. The analyti procedure was as follows:—

System $KCl—K_2Cr_2O_7—H_2O$.—The chlorine w determined by titration with $N/10$ silver nitrate, us potassium chromate as indicator. The end-po

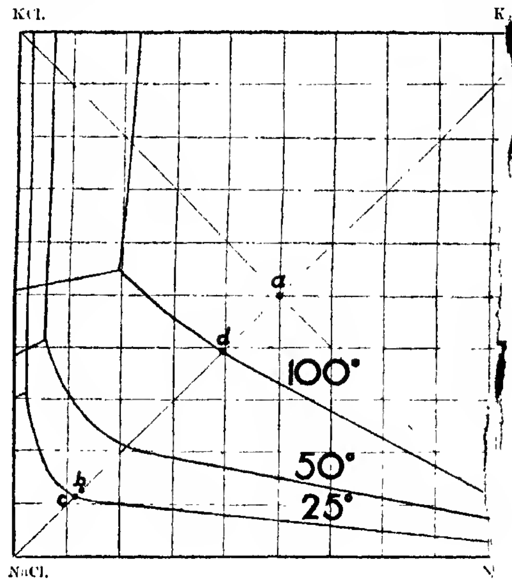

FIG. 1.

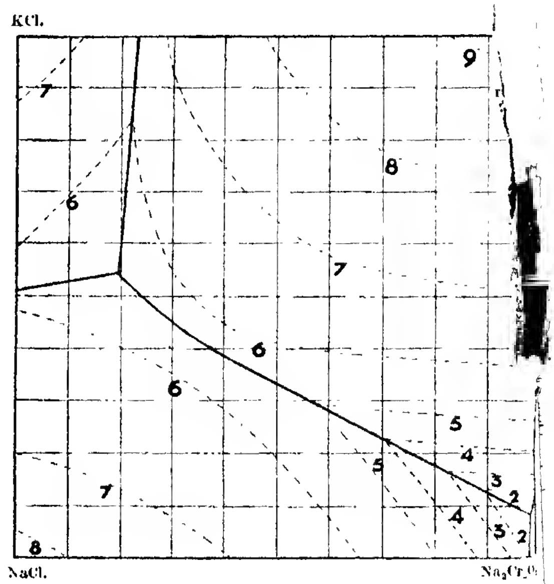

FIG. 2.

of the titration was quite definite and sharp, even in presence of considerable bichromate ion provided the solution was sufficiently diluted. Bichromate

s determined by liberation of iodine from potassium lide in a solution acidified with hydrochloric acid, d titration of the liberated iodine with $N/10$ thiolphate. These two determinations gave the perntages of potassium chloride and potassium bichrom- in the original solution and, by difference, its iter content.

System $NaCl$—$Na_2Cr_2O_7$—H_2O.—This was analysed a manner similar to the above.

System $K_2Cr_2O_7$—$Na_2Cr_2O_7$—H_2O.—The analysis his system involves a determination of the alkalis ent. This was done by the indirect method liquot part of the solution was reduced by alcohol r acidification with hydrochloric acid, and the mium precipitated as hydroxide by ammonia and oved by filtration. The filtrate was evaporated ryness, the ammonium salts were ignited off, the lue was dissolved in water and traces of carbonaceous matter and chromic oxide were removed by filtration through a small filter paper. The filtrate was collected in a crucible, carefully evaporated to dryness, and the residue gently ignited, and weighed. This gave the weight of mixed potassium and sodium chlorides. The residue was dissolved in water and titrated with standard silver nitrate. This gave the chlorine content, which allowed the relative proportions of potassium and sodium chlorides (and therefore of potassium and sodium bichromates in the original solution) to be calculated. Analyses of a known mixture of sodium chloride and potassium bichromate showed that the experimental error to be allowed for using this method was in the neighbourhood of 1%. All analyses in the system were checked by determining the bichromate content of each solution, and any in which this differed from the value calculated from the alkali determinations by more than 1% were discarded or repeated

System (K, Na)—(Cl, Cr_2O_7)—H_2O.—all four radicals were determined by the methods detailed above. As in each case equivalents K + equivalents Na must equal equivalents Cl + equivalents Cr_2O_7, and as, in general, complete agreement was not obtained, it was assumed that the Cl and Cr_2O_7 values were correct, and the values obtained for K and Na were increased or diminished accordingly so long as the total discrepancy did not exceed 1%.

The analytical results obtained are given below. Those marked with an asterisk are taken from the paper by Reinders (*loc. cit.*). Columns 1–4 give the weight of each salt or radical in grams per 100 g. of solution, and column 5 the weight of water. Columns 6–9 give the results expresed as equivalents and as proportional parts where equivalents K + equivalents Na = 1 and equivalents Cl + equivalents Cr_2O_7 = 1, and column 10 the number of g.-mols. of water associated with each gram-equivalent of total dissolved salts.

The isotherms are represented graphically according to Jänecke's projection in Figs. 1 and 2. In Fig. 1 all three isotherms are shown. In Fig. 2 the isotherm at 100° is represented alone, the broken lines in th diagram indicating the number of molecules of wate associated with one equivalent of total salts i solution. Fig. 3 shows models built in the form of sections of square prisms, where the heigh of any point on the surface is proportional to th water value for a solution having that composition These show the contours of the saturation surfaces

It will be seen from the diagram that at all tem peratures the salts potassium bichromate and sodiu chloride are the compatible pair, whilst the saturati surfaces of sodium bichromate and sodium chlor are in each case widely separated. As the tempe ture is raised the potassium chloride and sodiu chloride fields increase considerably in extent, t potassium bichromate field being thereby diminish The sodium bichromate field is in every case ve small. It is also noteworthy that at 50° and m so at 25° the intersection curves of the sodi chloride and potassium bichromate fields assu pronouncedly curved shapes.

Technical application.—The phase-rule diagram ly be employed usefully in the technical manu-ture of bichromate, as by its means the yield to expected on mixing any given solutions of sodium hromate and potassium chloride can be readily iculated. Further, the process of recovery of hromate from mother liquors by evaporation can controlled as will be shown.

The liquor from which the bichromate crystallises is prepared by adding an equivalent quantity of potassium chloride in solution to a solution of sodium bichromate of known strength. The resulting mixture according to the notation here used would then have the composition 0·5Na, 0·5K, 0·5Cl, 0·5Cr_2O_7. This is represented by point "a" in Fig. 1. Now at 25° such a mixture is associated with 26 mols.

FIG. 3.

H_2O and this is therefore the limiting concentration for crystallisation. Expressed in grams this solution would be 29·25 g. NaCl, 73·55 g. $K_2Cr_2O_7$, 468 g. H_2O, and would be obtained by dissolving 37·28 g. of KCl and 65·5 g. of $Na_2Cr_2O_7$ in 468 g of water. This solution contains 65·5 ÷ 570·78 or 11·5% $Na_2Cr_2O_7$ by weight. At 50°, 20·2%, and at 100°, 29·9% $Na_2Cr_2O_7$ would be required to give such a saturated solution. If the salts are mixed so as to produce more concentrated solutions at these temperatures there will be separation of potassium bichromate. The actual amount of potassium bichromate which will separate in any given case can be calculated as in the following example:—Suppose a mixture to be made up so that it contains 0·5 g.-equiv. KCl, 0·5 g.-equiv. $Na_2Cr_2O_7$, and 8·5 g.-mol. H_2O, *i.e.*, 37·28 g. KCl, 65·5 g. $Na_2Cr_2O_7$, 153 g. H_2O, or 14·6% KCl, 25·6% $Na_2Cr_2O_7$, 59·8% H_2O. This solution is supersaturated with regard to potassium bichromate and this salt will separate out, the composition of the remaining solution travelling along the line $K_2Cr_2O_7$—NaCl until it reaches a point where a solution of these two salts is in equilibrium with 8·5 mols. H_2O. This is the point "b," which has the composition 0·876NaCl, 0·124$K_2Cr_2O_7$, 8·5H_2O. The amount of potassium bichromate which is precipitated is given by the equation

$$0{\cdot}5K_2Cr_2O_7 + 0{\cdot}5NaCl = \underbrace{xK_2Cr_2O_7}_{\text{precipitate}} + \underbrace{y(0{\cdot}876NaCl + 0{\cdot}124K_2Cr_2O_7)}_{\text{solution "b"}}$$

Since the total quantities of each salt and of water remain unchanged and since no sodium chloride separates, $0{\cdot}876y = 0{\cdot}5$ or $y = 0{\cdot}571$, whence $x = 0{\cdot}429$. Thus from the original 0·5 equivalent of $K_2Cr_2O_7$, 0·429 equiv. has been obtained, or a yield of 85·8%.

Since the point "b" is very close to the boundary line between the fields $K_2Cr_2O_7$ and NaCl, it is apparent that a small increase in the concentration of the original mixture would cause this point to travel to "c" when potassium bichromate and sodium chloride would crystallise out together. The concentrations used in this example are thus about the maximum which could be employed in practice (working at 25°) if the risk of contamination with salt is to be avoided.

To remove the potassium bichromate still remaining in the mother liquor it is necessary to concentrate the solution. Suppose this is done at a temperature of 100°. It will be seen from the diagram that at this temperature the point "b" lies in the NaCl field and therefore, on concentration, salt will separate, the composition of the liquor passing along the line NaCl—$K_2Cr_2O_7$ towards the point "d." At "d" the solution becomes saturated with both sodium chloride and potassium bichromate, and if evaporation were further continued both would crystallise out together. Evaporation must therefore be stopped at this stage. Point "d" has the composition 0·609NaCl, 0·391$K_2Cr_2O_7$, 5·67H_2O. We therefore have the equation

$$0{\cdot}876NaCl + 0{\cdot}124K_2Cr_2O_7 + 8{\cdot}5H_2O = \underbrace{xH_2O}_{\text{water evaporated}} + \underbrace{yNaCl}_{\text{precipitate}} + z(0{\cdot}609NaCl + 0{\cdot}391K_2Cr_2O_7 + 5{\cdot}67H_2O)$$

Thus $8{\cdot}5 = x + 5{\cdot}67z$; $0{\cdot}876 = y + 0{\cdot}609z$; $0{\cdot}124 =$ $0{\cdot}391z$. Whence $x = 6{\cdot}7$; $y = 0{\cdot}683$; $z = 0{\cdot}317$. Thi[s] means that of every 8·5 mols. H_2O in the solutio[n] 6·7 mols. can be evaporated and that thereby sodiu[m] chloride is obtained to the amount of 0·683 ÷ 0·876 or 78% of the content of the original mother liquor.

On cooling the remaining solution to 25° agai[n] further potassium bichromate is precipitated, n[the] composition of the solution returning to the p[oint] "c." The equation governing the precipitation is

$$0{\cdot}609NaCl + 0{\cdot}391K_2Cr_2O_7 + 5{\cdot}67H_2O = xH_2O + yK_2Cr_2O_7 + z(0{\cdot}876NaCl + 0{\cdot}124K_2Cr_2O_7 + 8{\cdot}5H_2O)$$

whence $x = -0{\cdot}24$; $y = 0{\cdot}305$; $z = 0{\cdot}695$.

The negative value for H_2O shows that on coo[ling] such a solution crystallisation would not stop [on] reaching the point "c" and a precipitate [of] potassium bichromate contaminated with sod[ium] chloride would result. To prevent this it would [be] necessary either to add water to the extent [of] 0·24 mol. for each equivalent of total salts be[fore] cooling or to stop the evaporation at some [point] before the point "d" was reached. The am[ount] of potassium bichromate recovered by the a[bove] procedure would be 0·305 ÷ 0·391, or 78%. [The] total yield by the two crystallisations combin[ed is] therefore 85·8 + [78 × (100 − 85·8) ÷ 100] or 96·9[%].

THE CONTRACTION OF ALCOHOL O[N] DILUTION.

BY HERBERT P. FORAN, M.SC.

It is well known that when water is adde[d to] alcohol there is a contraction in volume, and [the] final volume of the mixture is somewhat less than [the] sum of the volumes of alcohol and water u[sed]. This contraction may generally be ignored in [the] laboratory, where the quantities employed are [re]latively small, but it cannot so easily be neglecte[d in] industry where large amounts of alcohol are b[eing] reduced in strength. Even in the laboratory [in] certain cases where great exactness is require[d it] must be taken into account.

There are tables published giving the amoun[t of] contraction corresponding to various dilutions, [but] as it happened that in several instances the amount[s] given differed considerably from those obtained by experiment, it seemed to be useful to devise a method whereby the correct amount of contraction could be ascertained by means of a simple calculation. The present investigation was undertaken with that object in view.

When water is added to alcohol the volume increases, the percentage of alcohol decreases, and there is a contraction in the total volume; the first two may be easily calculated. In order to be generally applicable, these factors must be expressed as percentages.

In the analysis of alcohol and spirits, it is usual to report the volatile constituents other than ethyl alcohol in grams per hectolitre of alcohol at either 100% or 50%. Thus, as a preliminary to the analysis, strength of the distillate must be brought to % by volume, and accurate tables have been piled giving the amount of water which must added to effect the reduction, as well as the l volume obtained. In Table I. the data in the . three columns are taken from the tables of ird and Cuniasse,[1] and from these the figures he remaining columns have been calculated.

ı this table the first column gives the percentage volume of the alcohol to be reduced. Column 2 s the number of c.c. of water to be added to c.c. of this alcohol in order to reduce it to 50% volume. The final volume obtained in c c. is n in column 3.

he fourth column shows the percentage increase volume (V), which, since the original volume 100, is the same as the volume of water added. ımn 5 gives the percentage of reduction in strength which is obtained from the formula $100\ (p-p')/p$, re p is the percentage strength of the original hol and p' the percentage strength after reduction ich in this case is 50%).

TABLE I.

%	Vol. water	Final vol	% Increase vol. (V)	% Reduction in strength (P)	Contraction c c.	Contraction % (C)	V/P
00	107·44	200 0	107 44	50 00	7 44	3 58	2 14
95	95·87	189·9	95·87	47·36	5·97	3 04	2·02
90	84·76	179 9	84 76	44·44	4 86	2 63	1 91
85	73 86	169 9	73 85	41 17	3 95	2 27	1 79
80	63·07	159·9	63·07	37 50	3 17	1·94	1 68
75	52 38	149 0	52 38	33·33	2 18	1 62	1 57
70	41 78	139·9	41·78	28 57	1·88	1·32	1 46
65	31·23	129 9	31·23	23 07	1 33	1 01	1 36
60	20 76	119·9	20 76	16 66	0 86	0 71	1 25
55	10·37	109·9	10·37	10 71	0 54	0 48	1 11

'he figures in column 6 represent the amount contraction, and are obtained by subtracting the final volume (column 3) from 100 plus the volume of water added (column 2). The percentage contraction (C) is given in column 7, and is arrived at by dividing the amount of contraction by the sum of the volumes of alcohol and water and multiplying the result by 100. The values obtained in column 4 (V) are divided by those in column 5 (P), giving the values for V/P set down in column 8

Having these data in tabular form, various attempts were made to trace a mathematical connexion between V, P, and C. Plotting V against C and P against C resulted in smooth curves, resembling somewhat a logarithmic curve. In other words, C was shown to be a continuous function of both V and P. Combinations of V and P were then tried, and it was finally seen that when the quotient V/P was plotted against C the result was a straight line.

In Fig. 1 the values of V/P obtained in Table I are plotted as ordinates and the corresponding values of C as abscissæ. The result is the straight line A B, the equation of which will be of the form $y=mx+c$. From the figure it will be seen that c is 1·02 and the value of m may be taken as 0·33. So the expression $y=mx+c$ becomes $y=0{\cdot}33x+1{\cdot}02$, whence $x=(y-1{\cdot}02)\div0{\cdot}33$, or $x=3(y-1{\cdot}02)$. Substituting C for x and V/P for y we have

$$C=3\ (V/P-1{\cdot}02).$$

By taking different values of V/P as found in Table I., and applying this equation, values for C were obtained which corresponded very well with those given in the seventh column. The results are shown in the following table:

TABLE II.

		C from Table I.	C calculated		Difference.
1	..	3 58	3 36	.	−0·22
2	..	3·04	3·00	..	−0·04

4	.	2 27	2·31		+0 04
5	..	1·94	1 98	.	+0·04
6	.	1 62	1 65	..	+0 03
7	.	1·32	1 32		—
8	..	1 01	1·02	..	+0·01
9	.	0 71	0 69	.	−0 02
10	..	0·42	0 36	.	−0 06

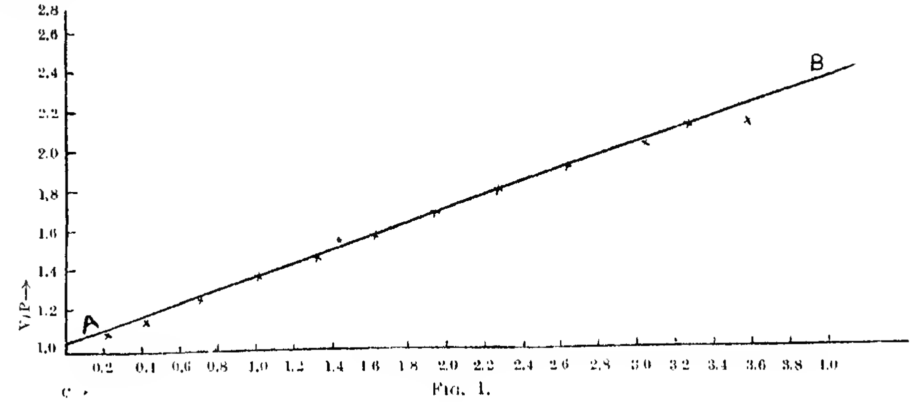

FIG. 1.

From these figures it will be seen that the values of C as calculated from the expression developed above do not vary from those calculated from experimental data by more than +0·06. The first line, where the reduction was from 100 to 50%, constitutes the only exception, the difference in this case being −0·22.

[1] C. Girard and L. Cuniasse, "Manual Pratique de l'Analyse des Alcools et des Spiriteux."

Thus far, however, the expression C =3 (V/P–1·02), has been applied only under the limited conditions governing the table of Girard and Cuniasse; that is to say, when the reduction was made from some higher percentage down to 50%. In order to ascertain whether it is equally applicable in the case of reductions to any strength, alcohol was diluted in various ways and the contraction observed. The results are given in Table III. The strength is here expressed in terms of fiscal proof spirit instead of % by volume.

2	65 O.P.	Proof	65·00	161·9	65·00	39·39	3·10	1·87	1·65
3	65 O.P.	15 U.P.	200·00	290·0	200·00	66·66	10·00	3·33	3·33
4	35 O.P.	20 U.P.	68·75	165·4	68·75	40·74	3·35	1·98	1·68
5	35 O.P.	30 U.P.	92·85	190·0	92·85	48·14	2·85	1·47	1·92
6	Proof	25 U.P.	33·33	132·0	33·33	25·00	1·33	0·99	1·33
7	40 O.P.	30 U.P.	100·00	195·0	100·00	50·00	5·00	2·50	2·00

The percentage contraction in each of these cases was then calculated from the expression C =3(V/P–1·02), and the calculated values were compared with those found experimentally, with the following results:

TABLE IV.

	C found	C calculated	Difference
1	0·59	0·60	+0·01
2	1·87	1·89	+0·02
3	3·33	6·93	+3·60
4	1·98	1·98	—
5	1·47	2·70	+1·23
6	0·99	0·93	–0·06
7	2·50	2·94	+0·44

It will be seen that in four cases (1, 2, 4, and 6) the agreement is reasonably good, the maximum difference being ± 0·06. In the other three instances (3, 5, and 7), the differences are so great as to make it apparent that in these cases, as well as in the one already cited (first line in Table II.), the method is unreliable.

When the values in Tables I. and III. of P, V, and V/P are tabulated together with the differences between the values of C as calculated and as found, the figures in Table V. are obtained:—

From this table it appears that the results are liable to be inaccurate when P is near or over 50%, when V is near or over 100%, and when V/P is near or over 2·00. It is suggested that the maximum limits of reliability be taken as 45% for P, 90% for V, and 1·90 for V/P.

TABLE V.

P	V	V/P	Difference
50·00	107·44	2·14	–0·22
47·37	95·87	2·02	–0·04
44·44	84·76	1·91	+0·04
41·17	73·85	1·79	+0·04
37·50	63·07	1·68	+0·04
33·33	52·38	1·57	+0·03
28·57	41·78	1·46	—
23·07	31·23	1·36	+0·01
16·66	20·76	1·25	–0·02
9·09	10·37	1·14	–0·06
18·18	22·22	1·22	+0·01
39·39	65·00	1·65	+0·02
66·66	200·00	3·33	+3·60
40·74	68·75	1·68	—
48·14	92·85	1·92	+1·23
25·00	33·33	1·33	–0·06
50·00	100·00	2·00	+0·44

The following example will serve to illustrate application of the method:—

It is desired to reduce 150 gallons of alcohol f 35 O.P. to 20 U.P. The volume of water to be ad to 100 c.c. of alcohol at 135% proof spirit to red it to 80% is given by the formula:—

$$135/80=(x+100)/100$$

whence x = 68·75 c.c.; hence the percentage incr in volume, V, is 68·75. The percentage decreas strength, P, is $[(135-80)/135]\times 100$, or 40·74. Th fore $V/P=68{\cdot}75/40{\cdot}74=1{\cdot}68$.

Applying the expression, $C=3(V/P-1{\cdot}02)$, we $C=3(1{\cdot}68-1{\cdot}02)=3\times 0{\cdot}66=1{\cdot}98$.

Since it is necessary to add 68·75 c.c. of wat 100 c.c. of alcohol, the amount to be added to gallons will be $68{\cdot}75\times 150\div 100=103{\cdot}125$ gal The percentage contraction is 1·98, and the sum the volumes of water and alcohol is 253·125; th fore, the contraction will be $253{\cdot}125\times 1{\cdot}98\div 1$0 5·011 gallons. As this is accurate to within ±0 the loss in volume due to contraction may be ta as 5 gallons. The final volume will therefore be

$$253\tfrac{1}{8}-5=248\tfrac{1}{8}\text{ gallons.}$$

Summary.

1. When alcohol is diluted with water, if the centage increase in volume is represented by V, percentage decrease in strength by P, and the centage contraction by C, then the latter may calculated from the formula:—

$$C=3\ (V/P-1{\cdot}02).$$

2. The values of C, calculated from this form are not reliable when P is over 45%, when V is 90%, or when the ratio V/P is more than 1·90.

When P, V, and V/P lie below these limits, h ever, the calculated values of C do not differ f those found experimentally by more than ±0·06.

LAMINE SALTS OF SOME SULPHONIC ACIDS OF THE BENZENE SERIES.
—BENZENEMONOSULPHONIC ACID.

BY C. M. KEYWORTH, M.Sc., A.I.C.

lamine salts of the naphthalene and anthra-ne series have been studied, notably by Perkin Sewell (J., 1923 27 T), Forster and Keyworth 24, 165 T, 299 T), and by Ambler (J. Ind. Eng. 1920, **12**, 1081) and Lynch (*ibid.*, 1922, **14**, 964). benzene series the arylamine salts have not studied, but alkylamine salts of benzene-luene-sulphonic acids have been prepared by and Westenhoff (Amer. Chem. J., **10**, 129). salts had low melting points and were charac-by their great solubility in water.

arylamine salts of benzenemonosulphonic acid owever, much less soluble in cold water, but the most part, easily soluble in hot water, hich they can be readily recrystallised They arp melting points with but few exceptions. ral they have higher solubilities and lower points than the corresponding arylamine naphthalenesulphonic acids.

erto these sulphonic acids have been identified nversion into the sulphochloride or sulphon-, or by fusing with caustic alkali and identify-e resulting phenol. Their identification can ried out more readily by means of a suitable ine salt. For example, the α- and β-naphthyl- salts of benzenemonosulphonic acid are formed and melt very sharply. Conversely quantities of amines may also be identified benzenemonosulphonic acid, in a similar way use of naphthalenemonosulphonic acids.

general the methods for the preparation of lts are similar to those used by Forster and orth for the preparation of the arylamine of naphthalenesulphonic acids (*loc. cit.*), but arium and calcium salts were mostly employed. ene was sulphonated with concentrated sulphuric at 80° and then allowed to stand 24 hours, the sulphonic acid was converted into the m or barium salt in the usual way. (By this od the amounts of disulphonic acids formed negligible.) Convenient quantities to use for ring salts are from 0·1 to 0·05 g.-mol, but a excess of the amine was found desirable. stallisation from water gave a pure product st cases.

The purity of the salts was checked, as with the lts previously described, by (1) melting point, 2) titration, and (3) solubility. The salts consist of 1 mol. of arylamine to 1 mol. of acid, except in he case of the diamines when they consist of 2 mols. of acid to 1 mol. diamine. The solubilities are expressed as parts per hundred (by weight) of salt dissolved in 100 parts of saturated solution All melting points are corrected.

Aniline benzenemonosulphonate To 24·5 g. of barium benzenesulphonate dissolved in 75 c.c. of hot water, 9·5 g. of aniline and 11 c.c. of concentrated hydrochloric acid were added. On cooling, fine needles were obtained which were easily recrystallised from a small quantity of hot water; m p. 240°. Solubility at 19°, 11·3/100; 0·5696 g required 20·3 c.c. of $N/10$ NaOH = 99·9% of theory.

o-Toluidine benzenemonosulphonate—This salt is very soluble in water and must be prepared in concentrated solutions, when long white needles are obtained, which can be conveniently recrystallised from alcohol: m.p. 176° Solubility 20/100 at 19°; 0·4662 g required 17·4 c.c. of $N/10$ NaOH = 100·2% of theory.

Norton and Westenhoff (*loc. cit.*) mention the aniline, *o*-toluidine, and α-naphthylamine salts of benzenemonosulphonic acid They give the m.p. of the *o*-toluidine salt 137°, and state that it is only sparingly soluble in water.

m - Toluidine benzenemonosulphonate — Beautiful long needles or elongated flat prisms, m p. 173°. Solubility 9·1/100 at 18°; 0·5356 g. required 20·3 c.c. of $N/10$ NaOH = 100·4% of theory.

p-Toluidine benzenemonosulphonate, white needles, m p. 205°, is easily prepared from the barium or calcium salt by the addition to the solution of sulphuric acid and *p*-toluidine. Solubility at 16°, 7·4/100; 0·7182 g. required 27·15 c c of $N/10$ NaOH = 100·2% of theory.

α-Naphthylamine benzenemonosulphonate. — Prepared from a freshly made solution of α-naphthylamine hydrochloride, this salt crystallises in fine white needles, m p. 234°, readily soluble in hot water. Solubility at 14°, 0·77/100; 0·7284 g. required 24·2 c c. of $N/10$ NaOH = 100·0% of theory.

β-Naphthylamine benzenemonosulphonate. — This salt is much less soluble in hot water than the α-naphthylamine salt, and a thick white precipitate is easily obtained on cooling a hot solution. Glistening white plates, m p. 248°. Solubility at 14° 0·59/100; 0·8112 g. required 26·95 c c. of $N/10$ NaOH = 100·0% of theory.

p - Nitro - o - toluidine benzenemonosulphonate.—Pale yellow needles, m.p. 222°. Solubility at 15° 1·84/100; 0·5110 g. required 16·55 c.c. of $N/10$ NaOH = 100·4% of theory.

m - Nitroaniline benzenemonosulphonate.—Yellowish plates, m.p. 236° (decomp.). Solubility at 15° 3·85/100; 0·3718 g. required 12·6 c.c. of $N/10$ NaOH = 100·3% of theory.

m - Xylidine benzenemonosulphonate was somewhat difficult to obtain in the pure state by recrystallisation from water, but it can also be recrystallised from alcohol, m.p. 233°. Solubility at 15° 1·46/100; 0·5832 g. required 20·8 c.c. of $N/10$ NaOH = 99·5% of theory.

Benzidine benzenemonosulphonate.—9 g. of barium benzenesulphonate dissolved in 50 c.c. of hot water were added to 3·7 g. of benzidine dissolved in 5 c.c. of hydrochloric acid and 100 c.c. of water. On cooling only slightly a precipitate was obtained which was recrystallised from 150 c.c. of water; m.p. above 330°. Solubility at 16° 0·59/100; 0·7348 g. required 29·25 c.c. of $N/10$ NaOH = 99·6 of theory (mol. wt. 560).

o - Tolidine benzenemonosulphonate. — Greyish-white plates, readily soluble in hot water, m.p. 310°. Solubility at 15° 1·45/100; 0·2788 g. required 10·55 c.c. of $N/10$ NaOH = 99·9% of theory (mol. wt. 528).

Dianisidine benzenemonosulphonate.—Grey needles, m.p. 277°, were obtained by recrystallising several times, using decolorising carbon (norit). Solubility at 18° 2·11/100; 0·5840 g. required 21·0 c.c. of $N/10$ NaOH = 100·7% of theory.

m-Phenylenediamine benzenemonosulphonate.—Very soluble in water, this salt is difficult to prepare and to recrystallise. Grey flat prisms, m.p. above 320°. Solubility at 17° 19/100.

p-Phenylenediamine benzenemonosulphonate. After decolorising the crude product, colourless glistening plates are readily obtained, which are much less soluble in water than the *m*-phenylenediamine salt, m.p. above 320°. Solubility at 10° 2·57/100; 0·5188 g. required 24·3 c.c. of $N/10$ NaOH = 99·3% of theor (mol. wt. 424).

p-Chloroaniline benzenemonosulphonate.—Readil prepared from aqueous solutions, this salt is easil recrystallised in the form of glistening white plat m.p. 235°. Solubility at 20° 2·51/100; 0·5320 g. re quired 18·55 c.c. of $N/10$ NaOH = 99·6% of theor

o-Chloroaniline benzenemonosulphonate, m.p. 204 is much more soluble in water than the *p*-chlor aniline salt.

ψ-Cumidine benzenemonosulphonate.—Easily re crystallised from water or alcohol, white needles, m. 217°. Solubility at 16° 2·03/100; 0·4944 g. requir 16·85 c.c. of $N/10$ NaOH = 99·9% of theory.

p-Anisidine benzenemonosulphonate.—12·3 g. *p*-anisidine, 17·7 g. of calcium benezenesulphonat 11 c.c. of hydrochloric acid, and 100 c.c. of water gav crystals on standing; on concentrating and r crystallising white needles were obtained, m.p. 182 Solubility at 16° 12·8/100; 0·9170 g. required 32 c.c. of $N/10$ NaOH = 99·8% of theory.

p-Phenetidine benzenemonosulphonate. — 9 g. calcium benzenesulphonate and 7 c.c. of *p*-phenet idine dissolved in 5 c.c. of hydrochloric acid an 40 c.c. of water gave beautiful clusters of needles o standing, which are extremely soluble in hot wate Recrystallised they melted at 171°. Solubility a 17°, 21/100; 0·6984 g. required 23·8 c.c. of $N/10$ NaOH = 100·5% of theory.

The N-substituted arylamines do not readily for salts with benzenemonosulphonic acid. Attempts t prepare the salts of *m*-nitro-*p*-toluidine and *β*-amin anthraquinone failed, whilst basic salts of th diamines could not be obtained in the pure state.

STUDIES IN THE ACENAPHTHENE SERIES. PART I.

4-AMINOACENAPHTHENE.

BY GILBERT T. MORGAN AND H. M. STANLEY.

Acenaphthene, one of the constituents of the higher fractions obtained in the distillation of coal tar, finds a useful application in the synthesis of vat dyes belonging to the Ciba Scarlet series.

A survey of the bibliography of this hydrocarbon shows, however, that comparatively few of its theoretically possible substitution products have so far been described. The mono-substituted derivatives are chiefly those containing substituents in (*para*) position 5, the predominance of this type arising from the orienting influence of the ethylenoid side chain.

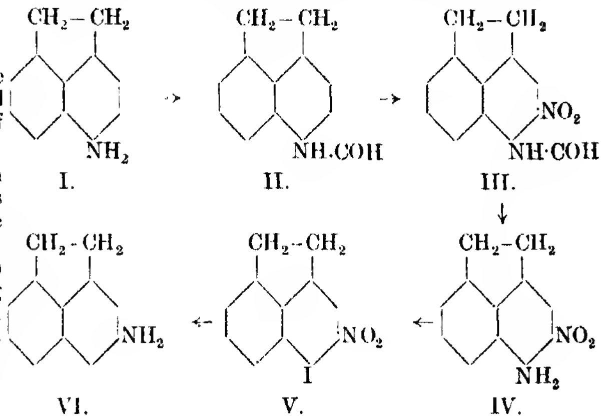
Nitration of the hydrocarbon as studied by Quincke (Ber., 1888, **21**, 1455) and by Graebe (Annalen, 1903, **327**, 77) led to 5-nitroacenaphthene, and reduction of this nitro compound furnished 5-aminoacenaphthene (Sachs and Mosebach, Ber., 1911, **44**, 2852; Fleischer and Schranz, *ibid.*, 1922, **55**, 3253).

Halogenation of acenaphthene follows a parallel course. 5-Bromoacenaphthene was first prepared by Blumenthal (Ber., 1874, **7**, 1095), whereas 5-chloro- and -iodo-acenaphthenes were described by Crompton, Cyriax, and Harrison (Chem. Soc. Proc., 1908, 41; 1910, **26**, 226). These three haloid derivatives were studied in greater detail by Crompton and Walker (Chem. Soc. Trans., 1912, **101**, 958), who established the identity of the chloro and bromo compounds with the corresponding substances obtained by Sachs and Mosebach from 5-aminoacenaphthene through the diazo reaction (Ber., 1910, **43**, 2474).

An important contribution to the chemistry of acenaphthene has recently been made by Dziewoński and Stolyhwo, who have amended earlier views on the constitution of acenaphthene monosulphonic acids (Ber., 1924, **57**, 1531). These investigators have shown that the sulphonic acid produced by the interaction of acenaphthene and chlorosulphonic acid in nitrobenzene is acenaphthene-3-sulphonic acid and not the 1-sulphonic acid as suggested in the patent literature in which this substance was first described (Kalle und Co., D.R.-P. 248,994; Friedländer, XI., 226). They also substantiate the constitution of acenaphthene-5-sulphonic acid, the product obtained in sulphonating with concentrated sulphuric acid by converting this product successively into 6-sulphonaphthalic acid and 6-hydroxynaphthalic acid.

* Read at a meeting of the Birmingham Section on November 11, 1924.

The present communication deals with the production of (*meta-*) *4-aminoacenaphthene* obtained by the operations summarised in the following diagram.



The acyl derivatives of 5-aminoacenaphthene (I.) nitrate in an ortho-position, as was demonstrated by Sachs and Mosebach (Ber., 1911, **44**, 2858), who hydrolysed 4-nitro-5-acetylaminoacenaphthene to 4-nitro-5-aminoacenaphthene and reduced the latter to the corresponding diaminoacenaphthene, which was shown to be an *o*-diamine by condensation with phenanthraquinone and diacetyl to give azino derivatives.

It has now been found that *5-formylaminoacenaphthene* (II.) nitrates smoothly to *4-nitro-5-formylaminoacenaphthene* (III.), which is hydrolysed readily to 4-nitro-5-aminoacenaphthene (IV.). The direct reduction of the diazonium salts of this nitro-amine to 4-nitroacenaphthene is not practicable and only ill-defined amorphous products are obtained.

The exchange of amino group for iodine is, however, readily effected through the diazo reaction, thus giving rise to *5-iodo-4-nitroacenaphthene* (V.). Drastic reduction of this product not only converts the nitro group into an amino radical, but also replaces the iodine by hydrogen, so that *4-aminoacenaphthene* (VI.) is obtained.

An attempt was made to produce 4-aminoacenaphthene by reducing the mononitro derivatives of 5-iodoacenaphthene, but this iodo compound nitrates in a very similar manner to 5-chloroacenaphthene (Farnell, Chem. Soc. Trans., 1923, **123**, 60), since in both cases the main product consists of a halogenated nitroacenaphthene containing the nitro group in the peri position with respect to the halogen. Accordingly drastic reduction of the less fusible *5-iodo-6-nitroacenaphthene* (m.p. 179°—180°) leads to 5-aminoacenaphthene.

The orientation of the nitro group in the more fusible 5-*iodonitroacenaphthene* (m.p. 151°—153°) has not yet been ascertained, although it is probably either in position 3 or 8; position 7 is less likely, as are also the positions 1 and 2 in the ethylenoid side chain.

EXPERIMENTAL.

5-*Aminoacenaphthene and acyl derivatives.*

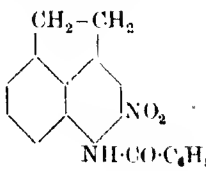
5-Nitroacenaphthene (Sachs and Mosebach, Ber., 1911, **44**, 2852) separated as a yellow crystalline mass on adding slowly 25 c.c. of nitric acid (*d* 1·42) to 25 g. of acenaphthene partially dissolved in 200 c.c. of glacial acetic acid, maintained at 10°. In this quantity of solvent the hydrocarbon dissolved on warming but separated on cooling and stirring as a fine crystalline magma which readily underwent nitration. After crystallisation from alcohol or petroleum the nitro compound melted at 106° (yield 84%).

5-Aminoacenaphthene (Fleischer and Schranz, Ber., 1922, **55**, 3253) was conveniently prepared by adding in two portions 50 g. of crystalline sodium hydrosulphite to 20 g. of 5-nitroacenaphthene dissolved in 200 c.c. of alcohol diluted with 100 c.c. of water, the mixture being boiled for 20 minutes until the yellow colour disappeared. After distilling off the alcohol, 100 c.c. of hot water and 100 c.c. of concentrated hydrochloric acid were added, the residue being boiled repeatedly with further addition of dilute hydrochloric acid. 5-Aminoacenaphthene, which separated on adding ammonia to the combined filtrates, was crystallised from light petroleum, m.p. 108° (yield 70%).

5-Acetylaminoacenaphthene (m p 192°, Sachs and Mosebach, *loc. cit.*) was nitrated to 4-nitro-5-acetylaminoacenaphthene (m.p. 251°) with nitric acid (*d* 1·42) in glacial acetic acid solution, but this product was not completely hydrolysed to 4-nitro-5-aminoacenaphthene even after 12 hours' boiling with alcoholic hydrochloric acid.

5-Benzoylaminoacenaphthene, which crystallised from glacial acetic acid in colourless plates (m p. 211°, Quincke, Ber., 1888, **21**, 1455), was prepared by the Schotten Baumann reaction and nitrated in glacial acetic acid to 4-*nitro-5-benzoylaminoacenaphthene* (VII., pale yellow needles from glacial acetic acid, m.p. 233°, yield 70%), but this product was not hydrolysable by hydrochloric acid even under pressure. The nitro group determined by titanous chloride gave NO_2=14·50; $C_{19}H_{14}O_3N_2$ requires NO_2=14·45%.

This nitrobenzoyl derivative was even more stable than the preceding nitroacetyl compound; it remained unchanged after heating with concentrated alcoholic hydrochloric acid.



VII.

5-*Formylaminoacenaphthene* (formula II.) was produced in almost quantitative yield (93%) by heating 5-aminoacenaphthene with 4 parts of formic acid (90% $H.CO_2H$) under reflux for one hour. After two crystallisations from dilute alcohol the product separated in colourless needles, m.p. 172°: found N=7·23; $C_{13}H_{11}ON$ requires N=7·11%.

4-*Nitro-5-formylaminoacenaphthene* (formula III. crystallised from glacial acetic acid in yellow needles m.p. 227°; it also dissolved in alcohol or chloroform It was prepared by adding 6·5 c.c. of nitric acid (*d* 1·42) to 5·0 g. of 5-formylaminoacenaphthene in 20 c.c. of glacial acetic acid at 10°. Considerable heat was generated and the yellow nitro product separated (yield 66%): found N=11·71 $C_{13}H_{10}O_3N_2$ requires N=11·57%.

4-Nitro-5-aminoacenaphthene (formula IV.) was obtained more readily from the preceding formyl compound than from its other acyl derivatives On heating under reflux 5·0 g. of 4-nitro-5-formylaminoacenaphthene in 75 c.c. of alcohol and 10 c.c of concentrated hydrochloric acid, the hydrolysis was completed in 30 minutes and the nitroamine separated in a state of purity from the dark red solution (yield 92%). 4-Nitro-5-aminoacenaphthene crystallised from alcohol or glacial acetic acid and melted at 219° (*cf.* Sachs and Mosebach, m.p. 222°—224°, *loc. cit.*): found N=13·16; $C_{12}H_{10}O_2N_2$ requires N=13·08%.

This nitro base was diazotised by adding 1·6 g to 8 c.c. of sulphuric acid (85% H_2SO_4) and to the suspension of amine sulphate were added 10 c.c. of glacial acetic acid, when a clear solution was obtained. To this solution cooled to 0°, solid sodium nitrite (0·75 g.) was added with stirring. Pieces of ice were introduced and the red diazo solution was poured into excess of absolute alcohol. On heating to boiling a flocculent red amorphous precipitate separated which did not melt below 270°.

5-*Iodo-4-nitroacenaphthene* (formula V.).—Six grams of 4-nitro-5-aminoacenaphthene suspended in 40 c.c. of 85% sulphuric acid were brought into solution by adding 50 c.c. of glacial acetic acid. After cooling to -5°, sodium nitrite (3·5 g.) and ice (200 g.) were added successively, followed by urea to destroy excess of nitrous acid and 6 g of potassium iodide in 15 c.c. of water. A brownish-grey precipitate separated and the mixture warmed to 70°: nitrogen was evolved and the coagulated solid extracted with boiling alcohol. On cooling, a crystalline product separated, a further amount being deposited on diluting with water (yield 45%).

5-*Iodo-4-nitroacenaphthene*, purified by successive crystallisation from alcohol and light petroleum (b.p. 80°—100°), separated in yellowish pink starlike clusters of needles, m.p. 148°. Insoluble in water sparingly soluble in glacial acetic acid, it dissolves readily in acetone, chloroform, ether or benzene found N=4·53, I=38·8; $C_{12}H_8O_2NI$ requires N=4·32, I=39·04%.

4-*Aminoacenaphthene* (formula VI.).—1. After unsuccessful attempts to reduce 5-iodo-4-nitroacenaphthene with sodium hydrosulphite and with hydrogen passed into alcoholic solution of the nitro compound in presence of finely divided palladium, the following

ocedure led to reduction of the nitro-group accom- nied by elimination of iodine.

Eight grams of 5-iodo-4-nitroacenaphthene, 10—15 g. granulated tin, 100 c.c. of concentrated hydro- loric acid and 100 c.c. of absolute alcohol were ated under reflux for half an hour when the solution came almost decolorised. After distilling off the cohol, the residual solution deposited the sparingly luble 4-aminoacenaphthene stannichloride, from hich ether and excess o. caustic soda removed the ee base.

Picric acid added to the ethereal extract preci- tated the yellow crystalline picrate (yield 60%).

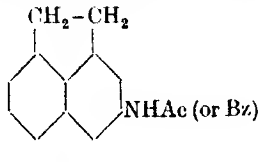
4-*Aminoacenaphthene picrate*, $C_{12}H_9{\cdot}NH_2,C_6H_2(NO_2)_3OH$, when recrystallised from alcohol or etone separated in yellow needles decomposing at 0°—200°. The picric acid content of this and other crates is readily determined by titration with andard sodium hydroxide using acetone as solvent d phenolphthalein as indicator, a small correction ing applied for the slight acidity of the acetone: und picric acid 57·7, C=53·62, H=4·25; $C_{18}H_{14}O_7N_4$ requires picric acid=57·54, C=54·27, =3·52%.

To isolate 4-aminoacenaphthene from its picrate, salt was added in small quantities to aqueous nonia warmed to 100°. After cooling to 0° the s was extracted with equal parts of ether and oleum (b.p. 80°—100°), the extract dried over um sulphate and distilled on the water bath; residual solution of base in petroleum was allowed vaporate until a mass of white crystals separated. product was recrystallised from hot water or alcohol, the former solvent yielding needles the latter giving prismatic needles, m.p. 87°. ninoacenaphthene is very soluble in the volatile nic solvents: found C=84·96, H=6·73, N=8·39; $_{11}$N requires C=85·21, H=6·51, N=8·28%.

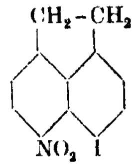
dilute mineral acids, 4-aminoacenaphthene otised to an almost colourless diazo solution, by differing from 5-aminoacenaphthene, which liazotisation yields a blue coloration. The new differs also from its isomeride in not developing rations with ferric chloride. Acenaphthene-4- zonium chloride couples with alkaline β-naphthol with resorcinol to red and orange-red azo pigments espectively.

4-*Acetylaminoacenaphthene* (formula VIII.). Dry -aminoacenaphthene (0·8 g.) was heated under reflux with 10 c.c. of acetyl chloride for 15 minutes, the solution poured into water, and the precipitate rystallised repeatedly from dilute alcohol or glacial cetic acid when it separated in colourless prisms, m.p. 175°—176° (yield 60%). Insoluble in water, this derivative dissolves in chloroform or acetone: found N=6·71; $C_{14}H_{13}ON$ requires N=6·64%.

4-*Benzoylaminoacenaphthene* (formula VIII.). One gram of 4-aminoacenaphthene was subjected to the Schotten-Baumann method of benzoylation. The white residue insoluble in water crystallised from 90% acetic acid and separated in prismatic needles, m.p. 196°, and having a faint yellow colour: found N=5·27; $C_{19}H_{15}ON$ requires N=5·13%.



VIII.



IX.

Nitration of 5-iodoacenaphthene. A yield of 60% of 5-iodoacenaphthene was obtained by adding slowly 51 g. of iodine to 30 g. of acenaphthene dissolved in 200 c.c. of hot alcohol containing 45 g. of yellow mercuric oxide. After boiling for 30 minutes the filtered solution and alcoholic washings from mercuric iodide and oxide were combined and cooled, when the crude product separated as a yellow oil which was extracted with chloroform to separate the iodo compound from adherent mercuric iodide. On evaporating off the solvent 5-iodoacenaphthene remained as a brown oil which solidified on cooling and was purified through its crystalline orange-yellow picrate, m.p. 100°, this compound being subsequently decomposed by ammonia (Crompton and Walker, Chem. Soc. Trans., 1912, **101**, 958).

Three c.c. of fuming nitric acid (d=1·50) were added to 10 g. of 5-iodoacenaphthene dissolved in 100 c.c. of glacial acetic acid at 15°, when the solution reddened and yellow crystals began to separate. After three weeks the yield of crystalline crude nitro product was 68%. 25 g. of this material when crystallised fractionally from glacial acetic acid (200 c.c.), yielded 11 g. of nitro compound (A) melting at 174° and 6·8 g. of nitro compound (B) with m.p. 153°.

Product A. 5-*Iodo-6-nitroacenaphthene* (formula IX.) After three additional crystallisations from glacial acetic acid, 7·0 g. were obtained in pale yellow prismatic needles melting at 179°—180°. This isomeride is sparingly soluble in alcohol but dissolves readily in other volatile organic solvents: found N=4·75, I=39·08; $C_{12}H_8O_2NI$ requires N=4·32, I=39·04%.

The orientation of the nitro group in 5-iodo-6-nitro- acenaphthene (m.p. 180°) is demonstrated by the following reduction: The nitro product A (5·5 g.) was heated under reflux for three hours with 150 c.c. of concentrated hydrochloric acid, 180 c.c. of alcohol and 20 g. of granulated tin. After removing alcohol the filtrate was cooled, when a sparingly soluble stanni- chloride separated. This double salt was decomposed with ether and excess of aqueous caustic soda, the ethereal extract of the free amine being treated with picric acid to precipitate the following picrate (yield 80%).

5-*Aminoacenaphthene picrate*, $C_{12}H_9{\cdot}NH_2,C_6H_2(NO_2)_3OH$, which resembled its isomeride (*ante*), was crystallised from alcohol and separated in yellow needles decomposing at 190°—200°: found picric acid=57·3, 57·8, C=54·14, H=3·69; $C_{18}H_{14}O_7N_4$ requires picric acid=57·54, C=54·27, H=3·52%.

When decomposed with aqueous ammonia this picrate yielded 5-aminoacenaphthene, which after crystallisation from hot water melted at 105°—106° (mixed m.p. with standard specimen=106°). Moreover, this preparation of the amine gave the blue colorations on diazotising and on treatment with alcoholic ferric chloride.

Product B. *5-Iodo-?-nitroacenaphthene.* After repeated crystallisations from glacial acetic acid, the more soluble and more fusible product separated in pale yellow needles melting at 151°—153°: found N=4·34, I=39·19; $C_{12}H_8O_2NI$ requires N=4·32, I=39·04%.

The amount of recrystallised compound so far obtained was too small to establish its constitution by reduction. The mixture of the two isomeric nitro compounds A and B forms a two-component system yielding mixed crystals; there is no definite evidence of any eutectic mixture. Although the analytical data point to a mononitro compound, it is doubtful whether this isomeride (m.p. 151°—153°) has been isolated in a completely homogeneous condition; the product is still under examination.

Since nitrated 5-iodoacenaphthenes containing the nitro group in positions 4 and 6 are described above, it follows that the foregoing isomeride must contain its nitro substituent in position 3, 7, or 8, nitration in the saturated side chain being excluded as highly improbable.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research for a grant which has partly defrayed the expense of this investigation; and also to Messrs. Hardman and Holden, Miles Platting, Manchester, for a generous gift of acenaphthene.

OBSERVATIONS ON THE HIGHER FATTY ACIDS.*

BY GILBERT T. MORGAN AND ARTHUR R. BOWEN.

I. The higher saturated fatty acids of cacao butter.

The object of this research was an investigation of the acids of cacao butter as a source of eicosanic acid. According to Traub (Arch. Pharm., 1883, **21**, 19—23) and Graf (*ibid.*, 1888, **26**, 830) cacao butter contains arachidic, stearic, palmitic, and lauric acids, but not theobromic acid, $C_{64}H_{128}O_2$, which had previously been reported by Kingzett (Chem. Soc. Trans., 1878, **33**, 38). Subsequently, Hehner and Mitchell (Analyst, 1896, **21**, 318) obtained pure stearic acid by repeated crystallisation in alcohol of the fatty acids from cacao butter. It has recently been shown by Ehrenstein and Stuewer (J. pr. Chem., 1923, (ii), **105**, 199) that arachidic acid derived from arachis oil is in all probability an *iso*docosanic acid, that is, a C_{22} acid having a branched chain, whilst the acid in rambutan tallow (from the seeds of *Nephelium lappaceum* J.) is the normal eicosanic acid (the C_{20} acid with unbranched chain).

Repeated crystallisation of the saturated cacao butter acids from 90% alcohol at 25° resulted in the isolation of pure stearic acid. This acid was also obtained by fractionation of the acids by Heintz's method.

For comparative purposes, pure eicosanic acid was prepared from erucic acid by potash fusion, and the mixed melting points with pure stearic acid were determined. Eicosanic acid was also obtained from rambutan tallow (Ceylon) and arachidic acid from arachis oil.

Saponification of cacao butter.—1 kg. of filtered cacao butter, 4 litres of absolute alcohol, and 500 g. of caustic potash in 2 litres of water were heated together under a reflux condenser in a copper vessel for four hours. After saponification, as much alcohol as possible was distilled off and the free acids were precipitated by the addition of a slight excess of 8*N*-sulphuric acid. At 50°—60° these acids separated as a pale yellow supernatant layer. The characteristic odour of cacao butter was retained after saponification. The free fatty acids were washed free from mineral acid, dried at 100°, and filtered.

Separation of saturated from unsaturated acids.—The saturated acids were separated from the unsaturated by means of the magnesium soap–alcohol method (Kerr, J. Ind. Eng. Chem., 1916, **8**, 904; Thomas and Yu, J. Amer. Chem. Soc., 1923, **45** (i), 113). Magnesium acetate (100 g.) was dissolved in 200 c.c. of boiling water, the solution filtered, coo[illegible] and mixed with three volumes of 95% alco[illegible]ate. One part of insoluble mixed fatty acids from c[illegible] butter was added to five parts (by volume) of [illegible] hot alcoholic magnesium acetate. The solu[illegible] was left overnight at room temperature, when [illegible] insoluble magnesium soaps were collected and wash[illegible] with cold absolute alcohol until free from magnesi[illegible] acetate. On decomposition with hydrochloric [illegible] these magnesium soaps yielded the fatty a[illegible] which after washing free from magnesium chlo[illegible] were dried at 100°.

Attempted separation of eicosanic acid from satur[illegible] cacao butter acids by recrystallisation from alc[illegible] at 25°. The saturated fatty acids from cacao but[illegible] (93 g.) recrystallised eight times from 90% alco[illegible] cooled to 25° gave 0·3 g. of acid, m.p. (Knap[illegible] method) 69·0°; mixed m.p. with stearic acid 69·0[illegible] Molecular weight by titration with *N*/10 alcohol[illegible] potash (1 c.c.= 0·006561 g. KOH): 0·0960 g. [illegible] acid required 2·90 c.c. of *N*/10 alcoholic potash: found M=282·6, $C_{18}H_{36}O_2$ requires M=284.

Fractionation of saturated cacao butter acids.

First fractionation.—The fatty acids of highest carbon content are the first to be separated by Heintz's method, which involves the fractional precipitation of their magnesium soaps by adding hot alcoholic magnesium acetate to an alcoholic solution of the fatty acids (J. pr. Chem., 1855, (i), **66**, 1). In this fractionation, 166 g. of saturated acids from cacao butter were dissolved in 500 c.c.

* Read at a meeting of the Birmingham Section on November 11, 1924.

f hot absolute alcohol and precipitated fractionally .y half the calculated amount of alcoholic magnesium ·etate. The precipitated magnesium soap was ›llected and the foregoing operation repeated five mes; the fatty acid thus obtained was thrice crys- ıllised from alcohol, when three grams of acid were ›tained melting at 69·0°. A mixed melting point ıth stearic acid was unchanged, whereas with cosanic acid the mixed melting point was 64°—67°.

Second fractionation.—In this fractionation, smaller ·antities (30 g.) of saturated fatty acids from cacao ·tter were used with 1½ litres of alcohol. Less ·oholic magnesium acetate was added than in the ·st fractionation, so that only about one-fifth of the ·ids were precipitated at each stage. The precipi- ·tion was carried out in duplicate and the small ·al fractions were combined; 0·3 g. of least soluble ·id was obtained from 60 g. of saturated acids. ·he melting point of this fraction was 68·5° and ·ixed melting point with stearic acid 68·5°, although ·e mixed melting point with eicosanic acid gave ·1 5°.

Preparation of n-*eicosanic acid.*

1. *From erucic acid* (Fitz, Ber., 1871, 4, 444).—›otassium erucate (40 g.) was fused with 114 g. f caustic potash and a little water at 310—320° ›r ¾-hour. The acid was separated as magnesium ılt; weight of crude acid, 26 g. After repeated ·ystallisation from petroleum (b.p. 80°—100°), ·e eicosanic acid (12 g.) melted at 75°; its methyl ·r melted at 46·5° and ethyl ester at 41·5°. Mole- · weight by titration gave M=311·3 · $C_{20}H_{40}O_2$ ·res M=312.

·*ced melting points of eicosanic acid stearic acid* ·*res.*—About 0·5 g. of the acids was melted, ·l, and allowed to solidify overnight in the ·cator. The melting points were then taken by ·p's method (J., 1915, 1121):—

·anic ·. ·$_{40}O_2$.	Stearic acid. $C_{18}H_{36}O_2$. %	m.p. °	Eicosanic acid. $C_{20}H_{40}O_2$. %	Stearic acid. $C_{18}H_{36}O_2$. %	m.p. °
	0	75·0	45	55	63·5
	20	70·5	40	60	63 3
	25	69·0	33·3	66 7	62·7
7	33 3	67·0	25	75	62·3
	40	64 5	20	80	63·5
5	47 5	63·5	9 8	90·2	66·7
	50	63 5	0	100	69 0

From rambutan tallow.—Rambutan tallow ·) was hydrolysed for four hours with 188 g. ›solute alcohol and 126 g. of 25% aqueous ·ic potash. The acids liberated with dilute ·lphuric acid were dried at 100°. The saturated ·cids were separated by the foregoing magnesium ·ap method; 42 g. of fatty acid were heated to ·iling with 250 c.c. of alcoholic magnesium acetate. ·he precipitated magnesium soap was decomposed ·th dilute hydrochloric acid, washed, and recrystal- ·ed from alcohol. This acid, which was still slightly ·llow, was decolorised by boiling with animal ·arcoal in petroleum (b.p. 80°—100°). The colour- ·s acid was recrystallised four times from light ·troleum: First crop, 0·7 g., m.p. 74·5°; second ·op, 6·0 g., m.p. 74°; third crop, 6·0 g., m.p. 68·5°. ·ethyl ester of acid from first crop, m.p. 45·5°.

Preparation of arachidic acid from arachis oil.—Arachis oil (50 g.) was worked up as in the case of cacao butter and rambutan tallow and the saturated fatty acids were separated as magnesium soaps. After four recrystallisations from light petroleum, the fatty acid (weight=1·5 g.) melted at 74°; mixed m.p. with n-eicosanic acid=67°—68°.

Summary.

The investigation was commenced in order to ascertain whether cacao butter could be used as a source of eicosanic acid, but fractional crystallisation of the free acids and fractional precipitation of their magnesium soaps did not lead to the isolation of any acid higher than stearic acid.

II. The existence of bimolecular complexes of the higher saturated fatty acids.

The melting points for the eicosanic acid–stearic acid mixtures were plotted against the percentage composition and the curve, Fig. 1, obtained. This type of curve indicates compound formation, in this case the bimolecular complex, 1 molecule eicosanic acid : 1 molecule stearic acid (composition =52·4% $C_{20}H_{40}O_2$, 47·6% $C_{18}H_{36}O_2$).

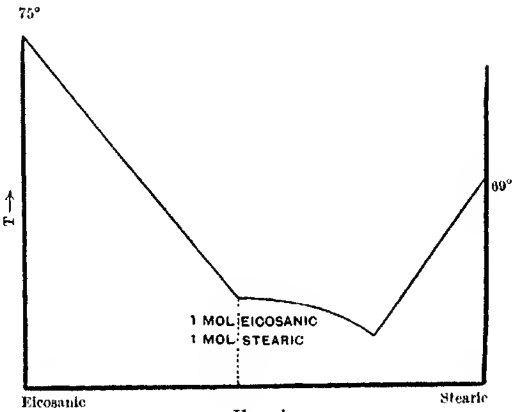

FIG. 1.
n-Eicosanic acid : stearic acid.

The corresponding stearic acid : palmitic acid curve was studied by de Visser (Rec. Trav. chim., 1898, 17, 182), who determined the melting points of mixtures of stearic and palmitic acids with a great degree of accuracy. Large quantities (50 g.) of the mixtures were used, and heated and cooled with stirring, the points of solidification giving the curve, Fig. 2. From this curve de Visser deduced that mixed crystals were formed in the vicinity of the 50% mixture. There is, however, no foundation for this conclusion, as the curve clearly shows compound formation (1 mol. stearic acid : 1 mol. palmitic acid). He also finds (*ibid.*, 346) that the composition of a mixture of the two acids in the proportion 47·5% stearic acid : 52·5% palmitic acid is unchanged on recrystallisation from alcohol and thus acts as a chemical entity.

Further determinations of melting points of fatty acid mixtures are given by Meyer, Brod, and Soyka

in their research on lignoceric acid (Monatsh, 1913, **34**, 1127) and by Meyer and Beer working on earth nut oil (*ibid*, 1202).

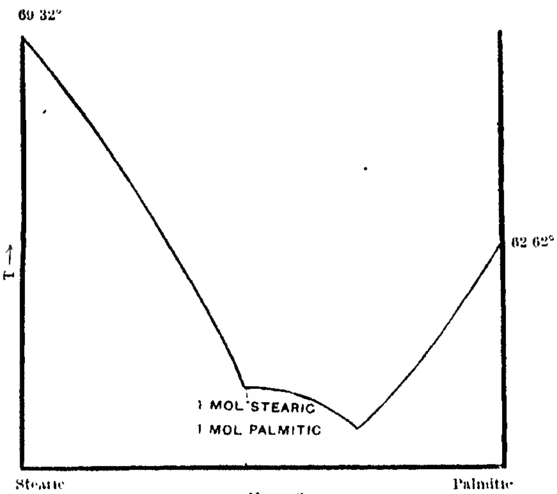

FIG. 2

Stearic acid: palmitic acid (De Visser).

Thus it will be seen that most of the examples of binary higher saturated fatty acid mixtures indicate marked evidence of compound formation usually of the type 1 mol. A : 1 mol. B, the amount of dissociation of these compounds at their melt points being considerable. It will, therefore, impossible to separate the 50% mixtures of su acids by fractional crystallisation, and the compour with their constant melting points and molecu weights will appear as chemical entities by t usual purity criteria. This is a point of gre importance in the identification of naturally-occurri higher fatty acids of both odd and even number carbon atoms. Holde (Ber., 1905, **38**, 1247) h shown that certain alleged instances of natura occurring heptadecylic acids are in reality mixtu of acids of even number of carbon atoms. In th connexion it is interesting to note that Müller a Shearer (Chem. Soc. Trans., 1923, **123**, 3156) ha also indicated that the higher fatty acids themselv are bimolecular, two chemical molecules constituti one crystal molecule. This result is confirmed the recent work of W. E. Garner and Randall on t heats of crystallisation of the normal monoba fatty acids (Chem. Soc. Trans., 1924, **125**, 881).

The authors desire to express their thanks to t Advisory Council of the Department of Scienti and Industrial Research for a grant which h partly defrayed the expense of this research; Messrs. Cadbury Brothers for a generous gift cacao butter; and to Mr. Petch, the Acting Direct of Agriculture, and Mr. Gadd, Peradeniya, Ceylo for the preparation of a sample of rambutan tallo

OURNAL of THE SOCIETY OF CHEMICAL INDUSTRY

XLIII., No. 50.] TRANSACTIONS [December 12, 1924.

NOTE ON "TEMPER" COLOURS.

BY R. C. GALE, A.C.G.I., A.I.C.

It is well known that when a piece of polished rdened steel is "tempered" by reheating, the heating is accompanied by the formation of a uence of coloured oxide films or "temper ours" on the surface of the metal. These colours y with the time of heating and with the tem- ature to which the metal is heated.

The observation of this phenomenon is a matter some antiquity; in the French translation[1] of inguccio's "De la Pirotechnia"[2] by Jacques ncent in 1556, the colours are described ". . . premiere desquelles a apparence blanche pour son dequoz il est appello argent. La seconde est jaune, est appelle d'aure. La tierce qui azuree, est nommee violet. Et la quatriesme de couleur cendree."

Robert Boyle[3] in 1680 writes: ". . . the Steel is hardened, will, if it be good, look somewhat hite, and must be made bright at the end, that change of Colours may be there conspicuous, l then holding it in the flame of a Candle . . . shall after a while see that clean end, which is contiguous to the flame, pass very nimbly ne Colour to another, as from a brighter , to a deeper or reddish Yellow, which arti- call a *sanguine*, and from that to a fainter nd then a deeper Blew." In a later chapter same work,[4] he observes ". . . touching the and Red and Yellow, that may be produc'd a piece of temper'd Steel: for these Colours h they be very Vivid, yet if you break the hey adorn, they will appear to be but Super- not only the innermost parts of the Metal, hose that are within a hair's breadth of the icies, having not any of these Colours, but ng that of the Steel itself."

ad[5] in 1900 showed that the colour of the film pendent on the nature of the substance, the perature of heating, and the time of heating, made use of these facts in differentiating between all areas of different constituents in pieces of lished metal, thus originating the method of heat tinting" now well known to metallographers.

Guillet and Portevin[6] in 1909 showed that for y given temperature, the colour developed tended become independent of time after a long period heating, further heating causing no change.

The possible explanations of the cause of colour the films are three:—

(1) Inherent colour of the oxide.
(2) Interference in the oxide film causing interference as in the case of Newton's rings and soap films.
(3) Diffraction of the incident light by the granular or laminated structure of the oxide film.

The first explanation is ruled out by the fact that the colour change does not take place at a definite temperature, and is not due to polymorphic change, *e.g.*, the mercurous iodide change red $\rightleftarrows$ yellow at 126°.

The two latter explanations have both been advanced in recent years.

Mallock[7] states that the colour cannot be due to interference, since it is not altered on reduction of thickness by polishing, this statement being quoted by Hinshelwood.[8]

This is contrary to the author's experience, who found that a dark blue film, purples and yellows were produced on polishing. It is not clear whether this is due to simple reduction of thickness, or to an irregular disturbance of the oxide film. Further work is in progress to clear up this point.

Hinshelwood[8] states that in the case of oxide films on copper, the colour is independent of the thickness of the film, and is probably due to diffraction of the incident light by the granular structure of the oxide.

Tammann[9] has investigated the rate of formation of coloured films produced by exposing metals to the action of air, nitrogen, halogens, etc., assuming that the thickness of the film of metallic compound formed is related to that of an air film of the same colour by the expression $T_A/T_M = \mu$, where T_A is thickness of the air film, T_M the thickness of the metallic compound film, and μ the refractive index of the metallic compound.

The apparently irreconcilable nature of the two latter explanations led the author to carry out the following preliminary experiments on the formation of temper colours on steel heated in air.

The primary object of the work was to determine the weight of the film formed by heating steel foil of known weight and area to a definite colour, and hence to deduce the thickness of the film and the ratio of its thickness to that of an oxide film of the same colour.

1. *Preparation of colour scale.*—A scale of colours was first prepared by heating mild steel discs $\frac{1}{4}$ in. by $\frac{3}{4}$ in. diameter, previously smoothed down to 0000 Hubert emery paper, in a molten tin bath for a period of one minute. The tin was contained in a steel tube $10 \times 1\frac{1}{2} \times \frac{1}{16}$ in. thick, sealed at the lower end, and immersed in a bath of stirred molten

potassium and sodium nitrates in equal weights. This bath was well lagged with asbestos wool and board, and heated by a gas burner. The temperature was gradually raised from 240° to 360° (uncorr.) in steps of about 5°, a steel disc being half immersed in the molten tin at each 5° increase of temperature.

This gave a series of colours varying from the palest yellow, through brownish-yellow to reddish-yellow, purple, blue, pale blue, and grey, some of the adjacent discs not differing perceptibly in colour or shade.

A series was then selected in which the differences in colour or shade between adjacent discs was sufficiently well marked to be used as a scale for comparison purposes, the discs then being numbered in sequence (see Table V.).

2. *Determination of the increase in weight of steel due to the formation of temper colours.*

Series I.—The material used was cold-rolled steel strip 0·0102× 7·5 cm. This was smoothed down to grade 0000 Hubert emery paper, cut into strips about 2×7·5 cm., and coiled into spirals by wrapping round a thin glass rod. The spirals were then washed with dry ether over lime in a Soxhlet extractor for 4 hours, about 30 washes being given. They were dried in a water oven at 98° for 1 hour, and cooled over phosphoric oxide in a desiccator.

Weighings were made on an Oertling assay balance, the spiral being counterpoised by gilt and platinum weights on the right-hand pan, a centigram rider on the left-hand beam, and a milligram rider on the right-hand beam. The position of the zero point was then determined by swings, using the formula $L=\frac{1}{8}(l_1+3l_2+3l_3+l_4)$, where l_1, l_2, l_3, and l_4 are consecutive readings on the pointer scale. A large number of readings was taken (about 25 releases), the zero points plotted against time, and the zero point estimated by extrapolation to the vertical axis. This was necessary owing to the increase in weight taking place as weighing proceeded, possibly due to the absorption of moisture on the surface of the metal, this surface being large compared with that of the counterpoise weights.

The spiral was then heated in an electric oven to 220° until a colour developed, re-weighed as before, and the colour matched by comparison with the colour scale.

These operations were repeated for three different colours, the results being summarised in Table I.

Weight of spiral, 1·2762 g.; density, 7·84 g. per c.c.; thickness, 0·0102 cm.; area, 31·9 sq. cm.

TABLE I.

Zero point.	Difference.	Colour.	Increase in weight. g. per 31·9 sq. cm.	Increase in weight. mg. per sq. m.
40	—	—	—	—
35·7	4·3	2	0·000036	11·3
33·9	6·1	6	0·000051	16·1
29·8	10·2	10	0·000086	26·9

Sensitivity of balance: 1 division on scale = 0·0000084 g.

Series II.—A further series of weighings was made with the object of obtaining greater uniformity of weighings than in Series I. This was attained by taring two spirals and using one as a counterpoise throughout the series of weighings and heatings, the variations in weight during weighings being much less than in Series I. After heat-tinting one spira both were then heated *in vacuo* at 180° for 10 minute and cooled in a desiccator over phosphoric oxide fo half an hour before weighing.

Weight of spiral, 1·075 g.; density, 7·84 g. per c.c thickness, 0·0102 cm.; area, 26·9 sq. cm.

TABLE II.

Zero point.	Difference.	Colour.	Increase in weight. g. per 26·9 sq. cm.	Increase in weight. mg. per sq. m.

39·0	6·2	6	0·000052	19·4
43·6	10·8	11	0·000091	33·7

Series III.—In this series of weighings steel stri 0·00254 cm. thick was used, prepared as in Series and II. The weighings were made on an Oertlin micro-analytical balance, equilibrium being obtaine by the use of riders as before. Owing to the greate increases in weight obtained, it was found possib to use the movement of the milligram rider on th right-hand beam as a means of approximating t equilibrium, the exact zero points then being dete mined by swings and plotted as before. An increa in the weight of the heated spiral during weig was observed.

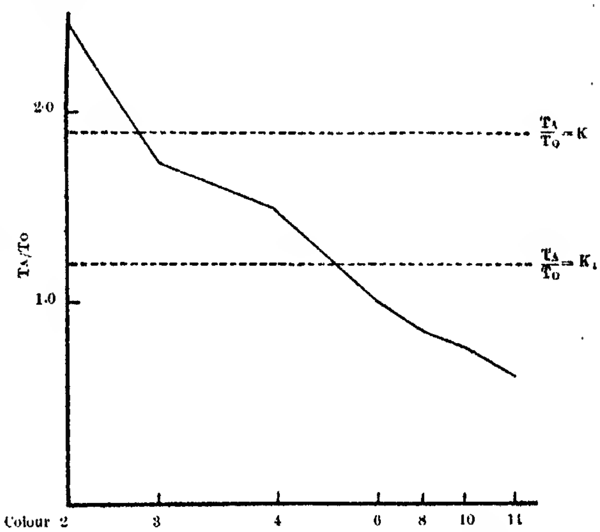
Fig. 2 shows the relative thicknesses of the air and oxide films, the colour scale being spaced to correspond with equal increments of thickness of an air film.



Colour.	$\frac{T_{air}}{T_{oxide}}$	Colour.	$\frac{T_{air}}{T_{oxide}}$
2	2·38	8	0·86
3	1·70	10	0·78
4	1·47	11	0·63
6	1·01		

FIG. 3.

Fig. 3 shows the ratios of thickness of air films to the thickness of oxide films of the same colour.

Summary and conclusions.

1. The thicknesses of "temper" colour films on steel have been determined by direct weighing, assuming that the density of the film is 5·25 g. per c.c. These vary from $4 \cdot 2 \times 10^{-7}$ cm. for a pale straw colour to $21 \cdot 3 \times 10^{-7}$ cm. for a dark purple.

2. For temper colours on steel, the ratio $T_{air}/T_{oxide} = \mu$ is not a constant for all colours, as assumed in Tammann's experiments, and therefore cannot be used to express the thickness of oxide films in terms of the thickness of air films of the same colour.

3. If the temper colours on steel are due to interference, it is necessary to assume that the refractive index of the film varies from 2·53 in the case of a pale straw colour to 0·63 in the case of a dark violet colour.

4. The fact that a blue film may develop purples and yellows when polished does not prove that the colours are due to interference, and further experiments are in progress to clear up this point.

5. The heat-tinted spirals increase in weight more rapidly than the unheated counterpoises when weighed in moist air. This supports the view that the film is granular in structure and is not an interference film.

The thanks of the author are due to Sir T. K. Rose, of the Royal Mint, for the loan of the balance used for Series I. and II. weighings, to Messrs. Jessops, and Messrs. Kayser, Ellison, of Sheffield, for the supply of the steel foil used in the experiments, and to the Commandant, Artillery College, for permission to publish these results.

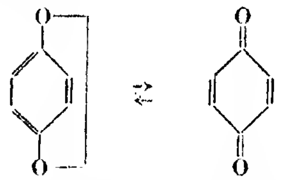
BACTERICIDAL ACTION OF QUINONES AND ALLIED COMPOUNDS.

BY GILBERT T. MORGAN AND E. ASHLEY COOPER.

In a previous paper (Biochem. J., 1921, **15**, 587), describing the bactericidal action of certain quinones, the authors suggested that the high germicidal power of benzoquinone was associated with the property of dynamic isomerism and due to the activity of the nascent peroxide molecules present in aqueous solutions.



Thus, although in the case of many groups of organic compounds, bactericidal power increases as the homologous series is ascended, the opposite was found to hold in the case of the quinones, *p*-benzoquinone being far more efficacious in this respect than the higher members of the series.

Further researches on this subject with A. W. Burtt and F. J. Corby are recorded in the present communication.

Influence of time on the relative germicidal power of the quinones.

The phenol coefficients of *p*-benzoquinone and toluquinone were first determined by the Chick–Martin method at 20°, with varying periods of disinfection :—

TABLE I.

Organism.	Substance.	Phenol coefficients. ½ hr.	1 hr.	3 hrs
B. typhosus	*p*-Benzoquinone	204	1400	>2750.
B. typhosus	Toluquinone	23	83	—
Staph. py. aur.	*p*-Benzoquinone	11	21	—

The results show that the bactericidal power of the quinones increases relatively to that of phenol when the period of disinfection is extended, coefficients of the unusual magnitude of 1000—3000 being obtained. It is thus of great importance to study the time-factor very carefully in these investigations.

Bactericidal power of various quinones and their derivatives.

The phenol coefficients were first determined with *B. coli communis* in absence of organic matter at 20°.

Bactericidal power was also determined another experimental method. It is well known t quinones react with proteoses and amino-ac and hence it was thought possible that suffici organic matter was carried over with a drop culture to affect the germicidal power of the quin solutions, as has been shown by Cooper, Woodhou and Forstner (unpublished work) in the case aldehydes, organic acids, and nitroso compounds.

The culture was therefore diluted with ste salt solution (0·85%) and a Chick–Martin t performed with this diluted culture. A gr difference in the results was obtained. With creasing dilution of the cultural organic mat there was a gradual increase in the germicidal pow of the quinone, until a certain limiting dilut had been reached, after which no further change the germicidal power was observed. To test whetl the consequent diminution in the number of orga isms present affected the results, the culture w diluted with sterile broth instead of with ster salt solution; the immediate effect was to low the germicidal power to its original value, showi that the disturbing factor was the organic mat present. The quinones to be compared were tested in this manner, and it was found that diluti of the culture 100 times was sufficient in each ca The main result of the observations is that t quinones retained approximately the same order regards germicidal power as when normal bro culture was employed, but the actual phenol c efficients were consistently much greater in magnitu A similar effect was observed when *B. pyocyane* was used in place of the *B. coli*, showing that t nature of the bacillus did not affect the change.

TABLE II.

Compound.	Coeff. at 20°, normal culture, ½-hour test.	Coeff. at 37°, culture dil. 100, 1-hour test. [With F. J. Corb
p-Benzoquinone	268	8650
Toluquinone	52	1710
Xyloquinone	< 20	296
Thymoquinone	< 20	356
m-Dichloroquinone	936	2620
Trichloroquinone	< 367	4130
Chloranilic acid	83·6	194·5
Sodium chloranilate	< 5·5	6·0
Bromanilic acid	—	216
α-Naphthaquinone	83	88·5
β-Naphthaquinone	104	663
Quinhydrone	—	517
Camphorquinone	Satd. soln. failed to disinfect.	1·6
Monochlorobenzoquinone	Satd. soln. failed to disinfect.	
p-Dichlorobenzoquinone	Satd. soln. failed to disinfect.	
p-Dibromobenzoquinone	Satd. soln. failed to disinfect.	

The following conclusions may be drawn fro the foregoing results :—

(1) Of all the quinones examined, *p*-benzoquinon is the most powerful.

(2) Camphorquinone, which is fully saturate and should not therefore exhibit the propert of dynamic isomerism, has a very low germ cidal power.

(3) The introduction of various substituents int the benzene ring results in a diminution i germicidal power (except in the case of *m*-d chloroquinone with ordinary culture).

With the phenols, however, bactericidal power i consistently increased by the substitution of haloge

hrlich and Bechhold, Z. physiol. Chem., 1906, 47, 3; Cooper and Woodhouse, Biochem. J., 1923, , 600), and in the case of phenols, alcohols, and nines also by the introduction of alkyl groups Iorgan and Cooper, 8th Int. Cong. Appl. Chem., 912, 19, 243). Again, 2.3-dihydroxynaphthalene is nsiderably more efficacious than pyrocatechol (*loc.* *t.*, 1912), whilst the naphthaquinones are less potent ian benzoquinone.

The effect of substitution in the case of *p*-benzo-uinone is thus in many cases quite anomalous, and he probable explanation is that its homologues nd other derivatives are less reactive and exhibit ynamic isomerism to a less degree (Kehrmann, er., 1888, 21, 3315; Stewart and Baly, Chem. oc. Trans., 1906, 89, 618).

(4) β-Naphthaquinone possesses a higher germicidal power than the isomeric α-compound.
(5) Bromanilic acid has a slightly greater activity than chloranilic acid.
(6) The germicidal power of chloranilic acid is greatly reduced by conversion into its sodium salt.
(7) The chloroquinones are more active as germicides than the alkyl derivatives (or homologues) of *p*-benzoquinone. As halogen substitution is known to be more effective than alkyl groups in diminishing the chemical reactivity of quinone, the abnormally high bactericidal power of the chloroquinones must be associated with a specific enhancement due to combined halogen, which easily counterbalances the depreciating effect of diminished tautomerism.

[With A. W. Burtt.] The exceptionally high ictericidal power of halogenated quinones is indi-ited by some further tests in which *B. pyocyaneus* s used. The coefficients obtained were as ws: benzoquinone, 15·6; toluquinone, <4·3; chloroquinone, 5·1. In this case the of halogen substitution is less marked, but with these results the halogen derivative is active than toluquinone, although halogen ituents reduce the chemical reactivity of nzoquinone to a greater extent than alkyl s. Further investigations with other organisms d be of interest. Incidentally, it may be observed t *B. pyocyaneus* resembles *Staphylococcus* in its ich greater resistance to the quinones than organ-ms of the coliform group (*cf.* Table I.).

Inhibitory power of the quinones.

Inhibitory power was determined with *B. coli communis* at 37° by the method described by the uthors (Biochem. J., 1923, 17, 30). The phenol coefficients of various compounds are tabulated below:—

TABLE III.

Phenol coefficients (48 hours' test).

p-Benzoquinone ..	35	*m*-Dichloroquinone ..	13
Toluquinone	27	Chloranilic acid ..	4·6
p-Xyloquinone ..	27	Benzoquinhydrone ..	97
Thymoquinone ..	11	α-Naphthaquinone ..	23
		β-Naphthaquinone ..	25

It is seen that the results obtained by the short-period disinfection test (Table II.) and the inhibitory method are entirely different, the compounds being consistently less active when tested by the inhibitory method. Whilst also the bactericidal power of benzoquinone is much greater than that of its homologues, the inhibitory powers approximate more closely. An extension of the period of disinfection, on the other hand, has already been shown to increase the difference in bactericidal action between *p*-benzoquinone and toluquinone, so that the relatively low inhibitory power of *p*-benzoquinone is probably due to its selective action on the constituents of the peptone broth.

Benzoquinhydrone is shown to be much more efficacious as an inhibitor than quinone itself. Probably the quinone is prevented from rapidly reacting with the peptone when in combination with quinol, and thus after adsorption is liberated within the bacterial cells in the active state available for disinfection. The quinhydrone may therefore be regarded as a quinone-carrier.

m-Dichloroquinone, although sometimes more active in the absence of organic matter than quinone itself, possesses a much smaller inhibitory power, and is unlikely to be of use for disinfecting purposes when organic matter is present.

Again, β-naphthaquinone is more efficacious as a germicide than the α-isomeride, but owing apparently to selective action of the β-compound upon the organic matter in the culture medium, the inhibitory powers of the two compounds are almost the same. This is confirmed by the results in Table II., which show that the α-compound is much less affected in germicidal power by dilution of cultural organic matter than the β-isomeride.

The inhibitory powers of *p*-benzoquinone and toluquinone have also been determined in other culture media as follows:—

TABLE IV.

Inhibitory phenol coefficients, *B. coli communis*.

	Benzoquinone.	Toluquinone.
Peptone broth	40	22
Peptone water (2%)	48	28
Urine	58	22
Ox-serum (heated 56°)	54	44
(Germicidal power, Chick–Martin test, in absence of organic matter)	6650	1710

In each case the coefficients are much lower than those obtained by the Chick–Martin test in absence of organic matter, indicating that the quinones are unlikely to be of service as internal disinfectants. There is also a relatively close similarity in the inhibitory powers of benzoquinone and toluquinone, especially in the case of serum, contrasting with the wider divergence in the germicidal power as determined by the Chick–Martin method.

The above observations suggest that there are substances present in the various media, either identical with or analogous to the vital cell constituents, with which the quinones react during the process of disinfection. These substances are present, principally in serum, and to a lesser degree in urine and peptone-broth. Further researches on these lines, employing for culture-media solutions of substances of known composition, should throw light on the

nature of the cell-constituents fundamental to vital phenomena.

[With A. W. Burtt and F. J. Corby.] *The action of quinones on proteins.*—The quinones, particularly *p*-benzoquinone, have been shown to react readily with proteins and allied substances, imparting a deep red colour to them (Cooper, Biochem. J., 1913, 7, 186). Gelatin when immersed in a solution of *p*-benzoquinone became permanently red and insoluble in water. The colour reaction diminished in intensity as the homologous series of quinones was ascended. Quinol was also found to be a product of the reaction, which supports the view that peroxide molecules of *p*-benzoquinone are especially involved in the chemical change.

Morgan and Cooper (1921) conducted further experiments with various proteins, and showed that *p*-benzoquinone was slowly removed from solution by proteins, a chemical action apparently taking place which proceeded continuously for several weeks.

Experiments to compare the rate of chemical action of *p*-benzoquinone and its homologues with gelatin have since been carried out, and the results are now described. The method employed consisted in submitting equal weights of gelatin to the action of equimolecular concentrations of the quinones, and determining the amounts taken up at the end of given periods. Other proteins, *e.g.*, caseinogen and albumin, have also been used. Full experimental details are given in the previous paper (*loc. cit.*, 1921).

The general outcome of these experiments is that benzoquinone reacts with gelatin to a slightly greater extent than toluquinone, but the difference in the rates of the reactions is only about 20%. It is evident, therefore, that the influence of dynamic isomerism so well brought out by the bacteriological results, is not revealed to the same extent in the protein experiments. Results of the same order were obtained in the case of *p*-xyloquinone; although benzoquinone is at least twenty times more active as a germicide than xyloquinone, yet its reaction with gelatin is at the most only twice as rapid as that of the higher homologue.

Different results were obtained when the colour reactions were further studied. Thus, solutions of benzoquinone cause gelatin to become intensely red, and in less than 24 hours to be insoluble in hot water. On the other hand, gelatin exposed to toluquinone solutions, although turning red, is not rendered insoluble until a week has elapsed, whilst xyloquinone has no effect on gelatin even after eight months.

The effect of tautomerism evident in the bacteriological results is thus also disclosed by the colour reactions of the quinones, but is not apparent in the foregoing experiments on velocity of reaction. It would appear that some definite chemical change associated with the tautomeric properties of the quinones underlies their bactericidal and colour-inducing activities, and that other reactions of lesser importance accompany this fundamental process, and thus obscure the significance of the quantitative data.

The qualitative colour tests are therefore of some interest, and further observations have been made.

The differences in the bactericidal powers of α- ar β-naphthaquinones were found to be reflected in the colour reactions with proteins, the α-quinone produ ing a light reddish-brown colour with gelatin an albumin, whilst the β-isomeride yielded a dark brow colour. Chloranilic and bromanilic acids behav differently from quinones towards proteins, on producing a reversible red coloration with gelati Being phenols, they also caused precipitation of th protein as an opaque mass. Monochloro-, *m*-dichlor and trichloro-quinones gave red colorations wit gelatin and albumin, whilst *p*-dichloro-, *p*-dibromo and camphor-quinones had no action.

The observations as a whole point to a correspon dence between germicidal powers and colour-inducin properties.

Summary.

1. The germicidal power of the quinones diminishe as the homologous series is ascended. Th naphthaquinones and camphorquinone are als less active than *p*-benzoquinone.
2. The results as a whole support the view that th high bactericidal power of *p*-benzoquinone i associated with its property of dynamic isomer ism, nascent reactive molecules being liberate in its aqueous solutions.
3. Certain halogenated quinones, however, are mor efficacious as germicides than the alkyl deriva tives, although they exhibit tautomerism to lesser degree. This exceptional behaviour i probably due to an enhancement in bactericida power resulting from the combined halogen atom present in the molecules.
4. The bactericidal power of the quinones is greatl reduced by the presence of organic matter, *e.g.* peptone, serum, urine.
5. Proteins give red colorations with solutions many quinones. These colour changes are ally irreversible and correspond in intensity the bactericidal power of the quinones.
6. Proteins react chemically with quinones. velocity of reaction does not appear, how to be determined entirely by the propert dynamic isomerism, and side-reactions of biological significance probably complicate results.
7. The comparatively high concentrations of the quinones necessary for disinfection in the presence of organic matter would seem to preclude the possibility of applying these substances a internal germicides in man.

The authors desire to express their best thanks to Prof. Ling, of the Department of Biochemistry of Fermentation, for his generous gift of halogenated quinones, and to the Advisory Council of the Department of Scientific and Industrial Research for grants which have helped to defray the expenses of this investigation.

.l. XLIII., No. 51.] [December 19, 1924.

CRITICAL STUDY OF THE PUBLISHED RESULTS OF TESTS OF WATER-GAS PLANT.*

BY M. W. TRAVERS, D.SC., F.R.S.

In working out a process for the complete gasifica-
n of coal, an account of which was recently pub-
hed in the *Gas Journal* by Mr. F. W. Clark and
author,[1] use was made of the published results of
perimental researches on the water-gas process
rried out by H.M. Fuel Board,[2] and by the Research
mmittee of the Institution of Gas Engineers.[3]
e results of these investigations were not at the
e considered in any way critically. Since this
per was published, it has been considered advis-
le to examine the published data relating to
ter-gas manufacture critically, particularly with
view to determine the influence of various factors
the efficiency of gas production. The study
s carried out entirely for our own information,
l with a view to improve our process for the
mplete gasification of coal, and not with a view to
blication. Least of all was it intended to criticise
se workers to whom we owe such quantitative
owledge of the water-gas process as now exists.
wever, it would be doing no service either to
m or to the gas industry to admit that experi-
ntal research has done more than lay a founda-
n on which knowledge of the water-gas process
1 be built up. A great deal of work, both in the
oratory and in the plant, remains to be carried
t, and in the meantime studies such as the following
y be of assistance to those who are planning
her experiments.

In the two reports referred to above, chemical
ermal balance sheets are used to show how the
y and material involved are utilised. Thus
ve :—

Credits	Debits
ble heat of coke	Sensible heat of water gas
nt heat of coke	Latent heat of water gas
ble heat of steam	Sensible heat of blow gas
ble heat of air	Latent heat of blow gas
	Sensible heat of waste, ashes, etc.
	Latent heat of waste, ashes, etc.

mething more than this is really required,
ticularly as such balance sheets have always
n based upon the assumption that the carbon
ccounted for as water-gas and waste in the
es left the plant as blow gas. What we really
nt is a statement of account which will really
w the relationship between the three sub-processes
which the water-gas process may be analysed,
l which are usually referred to as :—

(*a*) The blow process
(*b*) The run process
(*c*) The clinkering process

We will not include the "blow-run," an American device which would raise the CO_2-content to an extent inadmissible in English practice.

3. These three sub-processes can be considered as being conducted quite independently, and a statement can be prepared showing the debits and credits under each head of account, as below :—

	I. Blow	II. Run	III. Clinkering
Heat of reaction ..	..(+)A	(−)A′	(+)A″
Sensible heat of gas ..	(−)B	(−)B′	(−)B″
Sensible heat of air	..(+)C		(+)C″
Sensible heat of steam ..		(+)D′	
Sensible heat of coke	..(+)E	(+)E′	(+)E″
Sensible heat of ashes ..	(−)F	(−)F′	(−)F″
Radiation and conduction	(−)G	(−)G′	(−)G″

The capital letters refer to quantities of heat in any convenient units. The positive and negative signs, in brackets, indicate that so far as we are concerned at the moment, the numerical values of the symbols are positive or negative. The indices ′ ″ show whether the quantity refers to the blow, run, or clinkering process. If the relationship between the quantities is such that they represent the balance in the water-gas process, then

$$(A - A' + A'' + B + B' + B'' + C + \&c. \ldots) = 0.$$

4. The statement that the three sub-processes may be regarded as taking place independently may require a little explanation. In the blow process air is blown into the coke, and a quantity of heat represented by the algebraic sum of the quantities in column I. is rendered available, as sensible heat in the plant and its contents, for the conduct of the second operation. In practice we find that there is a limit to the period of the blow, and this is actually when the numerical value of negative quantities approaches the numerical value of the positive quantities. However, we are not at the moment in any way concerned with the mechanism of the process, or how the energy is stored up during the blow process. All we have to consider is that when a certain quantity of coke is gasified in the blow process, a certain amount of heat is rendered available for the run process, and this quantity, which will be denoted by the symbol P, is the algebraic sum of :—

A, which increases with the value of the ratio CO_2/CO in the blow-gas, since the heat of formation of CO_2 is greater than the heat of formation of CO;

B, which for any quantity of carbon gasified as blow-gas increases both with the CO_2-content of the blow-gas, and with the temperature at which the gas leaves the fuel bed;

C, which increases with the temperature of the air, and with the quantity consumed, but is an unimportant factor;

E, which depends upon the temperature of the coke;

F, which depends upon the temperature of the ashes removed from the plant, and the quantity of waste, a share of which is allocated to each part of the process;

* Read at a meeting of the Institution of Chemical Engineers on November 5, 1924.

[1] *Gas Journal*, October 3 and 10, 1923.

[2] *Fuel Board Technical Paper No. 7.*

[3] *Reports VI. and X.*

G, which depends upon the insulation of the plant, and the duration of the blow, relative to the duration of the run period.

5. Similarly the energy utilised during the blow, which we will denote by the symbol Q, is the algebraic sum of the quantities under column II. However, it is not necessary to go into details at this stage, except to point out that we shall simplify the problem by assuming that we are considering what may be called standard practice, in which a water-gas of a composition varying only between narrow limits, is produced (§10). In this case, for any definite quantity of carbon gasified as water-gas, A has a constant value, and the numerical value of B increases only with increase of the temperature at which the water-gas leaves the fuel bed of the plant.

6. We have supposed that the ashes removed in the clinkering process are debited to the blow and run processes in proportion to the quantity of carbon consumed in each, so as to allow us to deal with these processes independently. In the operation of water-gas plant in actual practice, we have, however, to take into account certain changes, some of which appear generally to be lost sight of. Published chemical balance sheets invariably show the amount of carbon removed from the plant during the clinker. This quantity, when subtracted from the total carbon supplied to the generator, is generally supposed to yield a measure of the total carbon gasified. The carbon gasified as water-gas is calculated from the measured volume and composition of the water-gas; and the difference between the total carbon gasified (assumed value) and the quantity of carbon in the water-gas is taken to be the carbon in the blow-gas.

Careful analysis of published results shows that quite a considerable loss may be incurred in the clinkering process through the combustion and loss of carbon which is not accounted for. Comparing the results of experiments recorded by the Research Committee of the Institution of Gas Engineers (§32), we find that, while the yield of water-gas in the test Report X, D, was much higher than in the mean of the tests Report VI., every factor upon which the efficiency of water-gas production depends, with certain minor exceptions, should have led to a higher production in the second case than in the first. However, in Test VI. the clinkering period was 14·2% of the whole test period, while in Text X, D, it was only 6·1%. This leads to an explanation of the fact that the total carbon gasified (run and blow) per 100 cub. ft. of water-gas made was recorded as 33·3 lb. in Test VI., and only 29·2 lb. in Test X, D. The difference is probably due to loss while clinkering which has been debited to the blow process.

7. The total loss of carbon must obviously include two quantities, the actual carbon removed from the plant, and the quantity consumed during the clinkering process. The latter is mainly converted into carbon monoxide by the draught of air entering the clinkering doors, the waste gases escaping through the stack valve. It will be noted that as the air current is a slow one, and as CO is therefore main product, and therefore,

(i) the loss of carbon is large relatively to quantity of air passing through the plant,

(ii) the heat developed in the process is relativ small, and a heat balance is rapidly attained betw the factors in column III.

It is probable therefore that we can neglect algebraic sum of the factors under column III., consider the carbon burned off while clinkering merely removed from the system. We will assu that we can do so to simplify treatment of the subje

8. If we take a ton of dry coke as the unit experiment, and suppose that this quantity conta M lb. of carbon, the carbon gasified as water-gas blow gas may be represented by (M—N) lb., wh N lb. is the quantity of carbon removed from plant as waste, and burned during the clinker process. For the purpose of obtaining numeri estimates we will at first suppose that the c contains 85% of carbon, and that about (7·03) of it is removed and lost during clinkeri The value of (M—N) is then 1800 lb. Neglect the small heat change (A″+B″, etc.) taking place the clinkering process, we can assume that a is arrived at in the water-gas process wh molecules of carbon are gasified as water-ore (150—x) lb.-molecules of carbon are gasva- blow-gas. If we write o a

$$p = a - b + e + e - f - g$$
$$-q = -a' - b' + d' + e' - f' - g'$$

where p, a, −b, are the numerical value of the syn used in paragraphs 3—5 when the same quan of carbon is gasified in the run and blow pro say, 10 lb.-molecules; then balance could be att when, $(150 - x)p = -x \times q$, or $x = 150\ p/(p$ We will now consider the blow and run proc separately, taking the run process first.

10. *The run.*—British water-gas practice, w we do not propose to criticise or to justify, ai the manufacture of water-gas approximating t following composition:—CO_2 5·5, CO 39·0, H_2 CH_4 0.5, N_2 6·0%.

The value of −q for 10 molecules of carbon gasif as water gas, must of course depend upon the position of the gas produced, but it will not, under or nary circumstances, vary very materially within small range over which the composition of water gas departs from the analysis given abo We can therefore eliminate one of the variables wh affect the efficiency of water-gas production, at expense, in a small degree, of completeness of analysis, but with the advantage of simplifying treatment of the subject enormously. As engine think of water-gas in terms of thousands of cub. at 60° F. (15·55° C.) and 30 in. of mercury, saturat we shall use these units throughout.

11. Taking the gas of the composition given ab as standard and assuming that 1000 cub. ft., 60° and 30 in., saturated is equivalent to 2·596 lb. ft. mo cular volumes, we have for each 1000 cub. ft. of g

	Lb.-mols. constituent	Lb.-mols. carbon
CO_2	0·14278 ..	0·14278
CO	1·01244 ..	1·01244
H_2	1·27204 ..	—
CH_4	0·01298 ..	0·01298
N_2	0·15576 ..	—
Total	2·59600 ..	1·16820

12. Since the basis of calculation is 10 lb.-mols. f carbon, this quantity is equivalent to 8560 cub. t. of water-gas at 60° F. etc., and contains :—CO_2 2222, CO 8·6666, H_2 10·8887, CH_4 0·1111, N_2 1·3333 .-mols.

13. If 85% of the steam supplied to tho generator decomposed we have from the abovo (per 10 lb.-ols.) :—Steam to generator, 13·0712; steam decomposed, 11·1109; steam with gas, 1·9603 lb.-mols.

14. The sensible heat of steam to generator (d′) = 0,950 C.H.U.

15. The heat of formation of water-gas (a′) can e calculated from the CO_2, CO, and CH_4 content f the gas, above, and the equations :—

$$C+2H_2O=2H_2+CO_2-20900 \text{ C.H.U.*}$$
$$C+H_2O=H_2+CO-31000$$
$$C+2H_2O=CH_4 \quad +20350$$

17. The evaluation of the minor factors e′, f′, and G′ will be dealt with later.

18. *The blow process.*—We will again take 10 lb.-molecules of carbon as our unit, but to avoid a vast amount of arithmetic, we will first suppose that the plant is blown with dry air, treating the effect of moist air separately (§ 26). We have now to consider the fact that the heat of formation of the blow gas, for any definite quantity of carbon gasified, varies very materially with the nature of the product, whether rich in carbon monoxide or rich in carbon dioxide. We have, therefore, to consider the heat of formation (a) to be a variable, and the best we can do towards simplifying the problem is to find a convenient way of connecting the value of a with the composition of the blow-gas. This can best be done by representing the molecular composition of the blow gas by $CO_2/CO=(10-n)/n$, where n lb.-molecules of carbon monoxide are produced for each 10 lb.-molecules of carbon gasified. This system has the advantage of giving us linear relationships. We will then calculate the values of a, b, and c, for values of the CO_2/CO ratio between 1/9 and 9/1. The data will be found in the following table :—

	CO_2/CO ..	1/9 ..	3/7 ..	5/5 ..	7/3 ..	9/1

at of formation of water-gas (−a′) = −291,950 U.

. The sensible heat of the water-gas leaving the depends upon the efficiency of the heat interge between the water-gas and the coke in the r layers of the fuel bed. It is a variable quantity ry material importance. It can be calculated the data given above in the manner indicated r previous paper (*loc. cit.*, p. 1). The following the values between 400° and 1000° C. :—

Temperature. ° C.		Sensible heat of water-gas. (−b′)
400	..	— 68700 C.H.U.
600	..	—104900
800	..	—142350
1000	..	—181100

*Coke carbon is assumed to be a form of carbon approaching graphite. amorphous carbon were used in the water-gas process one might write or the main reactions :—

(i) H_2O (steam) $= H_2O$ (water) $+(10725-10t°)$
(ii) $2H_2+O_2 = 2H_2O$ (steam) $+57785$
C (graph.) $+O_2 = CO_2 +94270$
(iii) $2CO+O_2 = 2CO_2 +67935$
(iv) C (graph.) $+H_2O = CO+H_2 -31450$
(v) C (amorph.) $= C$ (graph.) $+h$

h has a maximum value about 2350 for material like sugar charcoal, but as the change represented by equation (v) is independent of the reaction taking place between the gases and the coke, increases in velocity at high temperature, and is catalysed by ash, it is quite possible that, if the material used is amorphous carbon, more than an equivalent of the free energy of reaction (v) becomes available during the blow, and less than an equivalent set free during the run. This is a complication which has not yet been considered. The following values for the main reaction have been used : $C+O_2=CO_2+94750$; $C+H_2O=CO+H_2-31000$.

19. *Minor gains and losses.* The sensible heat of the coke at 20° C. equivalent to 10 lb.-molecules of carbon is given by :—

$$e \text{ or } e'=10\times12\times0{\cdot}195\times20/0{\cdot}85=550 \text{ C.H.U.}$$

assuming that the coke contains 85% of carbon. Assuming that it contains 12% of ash the sensible heat of the ashes at 300° is given approximately by :—

$$-f \text{ or } -f'=-10\times12\times12\times0{\cdot}2\times300/85=\text{say, } -1000 \text{ C.H.U.}$$

The radiation and conduction loss is taken as 2% on the calorific value of the fuel, distributed 1/3 to the blow process and 2/3 to the run process, as the loss depends upon the time of operation. We have then,

$$-g=-12000 \text{ C.H.U.}; \ -g'=-24000 \text{ C.H.U.}$$

20. Assuming that the composition of the water-gas corresponds to the analysis in § 13, and that p and −q represent each 10 lb.-molecules of carbon gasified in the blow and run processes respectively, we can calculate their values when the following facts are known :—The temperature at which the blow-gas leaves the fuel bed; the temperature at which the water-gas leaves the fuel bed; the ratio CO_2/CO in the blow-gas. The results are given in the following table :—

21.

Temperature. °C.	$-q = a' - b' + d' + e' - f' - g'$
400	−374150
600	−410350
800	−447800
1000	−486550

22.

CO_2/CO	1/9	3/7	5/5	7/3	9/1
Temperature. °C		$p = a - b + c + e - f - g$.			
600	198800	315500	432300	548950	661400
800	152750	262350	371350	480500	585350
1000	105450	206950	308500	409900	507100

23. If the coke contains M lb. of carbon per ton, of which N lb. are lost, then $(M-N)/12$ lb.-molecules of carbon are gasified as blow-gas and water-gas (§ 11), and the quantity of carbon gasified as water-gas is given by :—

$$x = (M-N)\ p/12(p+q).$$

In standard water-gas practice, 1000 cub. ft. of gas at 60° F. etc. have been assumed to contain 1·1682 lb.-molecules of carbon (§ 14), so that if $(M-N)$ is 1800 lb., or 150 lb.-molecules.

$$\text{volume of water-gas per ton of coke} = 150 \times 1000\ p/1{\cdot}1682\ (p+q) = 12840\ p/(p+q)$$

24. In order to show how the variation in the composition of the blow-gas and the temperature at which gases leave the fuel bed should affect the production of water-gas we have used the formula at which we have just arrived to calculate the volume of water-gas produced, when, as seems to be usually the case, the blow-gas leaves the fuel bed 200° hotter than the water-gas, the latter in the three series being at 400°, at 600°, and at 800° respectively. Calculations have been made for the five values of the ratio CO_2/CO which we have already dealt with. The results are set down in the following table.

CO_2/CO in blow-gas		1/9	3/7	5/5	7/3	9/1
Blow-gas	Water-gas	Volumes water-gas				
600°	400°	44550	58750	68800	76350	82850
800°	600°	34850	50050	61050	69250	75500
1000°	800°	24450	40600	52400	61350	68200

The figures relate to the case in which the loss of carbon is reckoned at 7% of the whole. Similar calculations have been made for the cases in which the loss of carbon is 14% and 21%, and the results of these three sets of calculations are shown in Fig. I. The shaded portion of the curves corresponding to a loss of 14% probably represents the range and limits of practical working.

25. That the output of water-gas per ton of coke should increase with increase in the value of the CO_2/CO ratio for the blow-gas and should decrease with increase in the temperatures at which the gases leave the fuel bed, is a conclusion which can be arrived at from the general consideration of the changes involved in the process. These facts are now demonstrated quantitatively. From our general knowledge of the process of the gasification of carbon by air it might also have been predicted that the CO_2/CO ratio for the blow-gas would increase with the velocity of the blast into the fuel bed, and might also decrease with increase in the depth of the fuel. However, in none of the experiments of which the results have been published have the depth of fuel and the blast velocity been varied independently. For instance, in the experiments described in Technical Paper No. 6 of the Fuel Research Board, the following data are given or can be deduced from the recorded facts.

	Depth of fuel bed ft.	Air per min. cub. ft.
Test 3	4	4740
Test 4	7	3310

The reduction in the velocity of flow is a onsequence of increasing the resistance of the fuel ed.

26. The effect of moisture in the air on the efficiency f the water-gas process cannot actually be neglected, hough the application of the necessary correction ould have involved a vast amount of arithmetic. he following calculation based upon the case in hich the air was half saturated (54%) at 6·5° C. indicates the magnitude of the effect proуced. In this case the air contains :—

	Lb.-molecules
Oxygen	0·001112
Water	0·0000275

27. We can suppose that the water is decomposed ompletely, yielding 0·0000275 lb.-molecule each f hydrogen and carbon monoxide. We can then ork out by the laborious process of trial and error e quantity of carbon monoxide and carbon dioxide roduced by the oxygen in the mixture. We will ke the case in which the ratio of the total CO_2 to e total CO is 5/5. We have then :—

	CO	CO_2	H_2
rom 0·0000275 H_2O ..	0·0000275	—	0·0000275
rom 0·001112 O_2 ..	0·0007225	0·0007498	—
Total	0·0007500	0·0007498	0·0000275

For 10 lb. molecules of carbon

eat of formation of H_2 and CO from water
$-666/7 \times 0·0000275 \times 31000 = -5700$

eat of formation of CO from oxygen
$666/7 \times 0·0007225 \times 26830 = 129200$

eat of formation of CO_2 from oxygen
$6667 \times 0·0007498 \times 94760 = 473700$

Total 597200

Where the air is supposed to be dry (§ 22), the eat of formation of the blow-gas for the CO_2/CO tio 5/5 was found to be 607950.

. To demonstrate the effect of moisture in air we will take the particular case in which the peratures of the blow-gas and water gas were and 600° respectively. We have now :—

	Air 54 % saturated	Air dry
p	360600 ..	371350
q	410350 .	410350
(p + q)	770950 .	781700
Volume water-gas ..	60050 ..	61050

The difference amounts to 1000 cub. ft. per ton of coke.

29. This calculation shows how important it is o avoid condensing moisture in the plant. Leakage of steam into the generator during the blow may also reduce the efficiency of gas production very considerably.

30. It is obvious that preheating the steam used in the run process must increase the efficiency of gas production, and on the other hand, that wet steam must have the opposite effect. In order to investigate the effect of preheating and of saturation we will take cases between the extremes of preheating to 700° C. and 10% saturation. Thus, for 10 lb.-molecules of carbon gasified we have for sensible heat of steam to generator (§§ 16, 17) :—

	C.H.U.
1. Steam preheated to 700° C.	78400
2. „ „ „ 300° C.	32650
3. „ dry at 100°	10950
4. „ 5% saturated	3650
5. „ 10% „ ..	—3650

31. If we take as an example the case in which the ratio CO_2/CO is 5/5, and the blow-gas and water-gas leave the fuel bed at 800° and 600° respectively, we have :—

	1	2	3	4	5
p.(800°)CO_2/CO=5/5)	371350	371350	371350	371350	371350
q.(600°)	342900	388650	410350	417650	425050
p+q	714250	760000	781700	789000	796400
Volume of water gas	66750	62750	61000	60450	59850

32. There are three very weak points in all investigations on water-gas production, the results of which have not as yet been published. These are due to :—

(i) failure to measure the amount of air entering the plant,

(ii) lack of means of recording loss of carbon,

(iii) inaccurate estimation of the sensible heat of the gases leaving the plant.

If the volume of air entering the plant were measured it would then be possible to check the

quantity of carbon gasified in the blow, which has hitherto only been arrived at as a difference. There is no doubt that the loss of carbon in clinkering, and otherwise, may be large; and with a view to illustrating this point we will again refer to the experiments mentioned in § 6. Some of the more

important data relating to these experiments are tabulated on p. 359 T.

33. In these two tests the rate of production of water-gas was almost identical—viz., 27520 and 27400 cub. ft. per hour of gas making, the difference being hardly outside the possible error of measurement. The difference between the compositions of the water-gas and blow-gas was very small, and every factor influencing the efficiency of gas production points to a higher efficiency in the Test VI. Yet the output of water-gas in this test was very considerably lower than in Test X, D. Careful analysis of the results gives no explanation of the apparent discrepancy, which appears to be in some way connected with the fact that in Test X, D, clinkering occupied only 6·1% of the total period of the test, whilst in Test VI. it occupied 14·2% of the period. A water-gas generator cannot be kept open for long periods without the combustion of a considerable quantity of fuel taking place in it. This may in some measure account for the difference in the yield of water-gas, which has certainly nothing to do with the change in the depth of the fuel bed.

34. With a view to ascertain the cause of the apparent discrepancies we have worked out balance sheets for the two tests on the lines which we have indicated. The facts recorded in the Reports Nos. VI. and X. have been accepted as published, and it has only been necessary to make an independent estimate of the loss by radiation and conduction, which is taken as 2% of the calorific value of the fuel. This is twice the allowance usually made in gas-producer practice. The total loss by radiation has been allocated to the blow and run process in the proportion 1/4, the ratio of the blow and run periods. The balance sheets refer to a ton of dry coke. This was to be expected.

P+Q = 1409450

35. The difference between the algebraical sum of the quantities under the headings Blow and Run for Test X.D. is relatively small, and of the sign which would have been anticipated, since errors in the temperature measurements, and loss of carbon, would tend to make the algebraic sum positive. The error is of the order of 10%, and with a view to ascertain the cause of it we first adjusted the results on the basis that the temperature measurements were 100° too low both for the run and blow processes. We then obtained the following result:—

	C.H
Sensible heat of blow-gas 700°	130
,, ,, ,, water-gas 620°	84

Introducing these quantities into the balance we obtain the result:—

	C.H
Total of quantities under blow (P) ..	294
,, ,, ,, ,, run (Q) ..	297

We have now run past the balance point. assume that about 5 per cent. of the carbon is assumed to be gasified as blow-gas is real and that the gases really leave the fuel be temperature about 50° hotter than is re by the pyrometers, we shall arrive at balance.

36. For the series VI. (mean) the value of is very large, a circumstance which is probably connected with the long clinkering period and the consequent loss of carbon, which is set down as carbon gasified in the blow process. This makes the calculated value of the heat of formation of the blow gas too high, whilst the fact that the temperature observations are probably too low makes the apparent numerical values of the sensible heat of the gases too small. It must be remembered th the investigation described in the Sixth Re of the Institution of Gas Engineers was carried on a public utility plant, without interfereing the operating routine, and the authors have n regarded it as covering much more than a gen test of the efficiency of the process.

37. Finally, since the water-gas produced Test X.D. approaches in composition to what have considered to be the standard (10), we apply the formula which we developed in the earl part of the paper to recalculate the water-gas output in this test. The result is as follows:—

1.	Water-gas per ton of coke, dry	57690 cu. ft.
2.	Carbon gasified per ton of coke	1726 lb.
3.	Water gas per 1800 lb. carbon	60130 cu. ft.
4.	Temperature blow-gas + 100°	700° C.
5.	,, water-gas + 100°	620° C.
6.	P, from table in § 28	383200 C.H.U.
7.	Q, from table in § 28	417850 C.H.U.
8.	Volume of water-gas from formula § 28 ..	61420 cu. ft.

The agreement between items 3 and 8 is as close as can be expected.

38. We can now deal with the experiments of which the results are published in Technical Paper 6 of the Fuel Research Board. These were carried out

vith a view of contrasting the Dellwik-Fleischer ystem of operation, in which a high blast velocity nd a shallow fuel bed are used, with the usual method f operating a Humphries and Glasgow plant, in which the fuel bed is of the order of 6 ft. to 7 ft. s has already been pointed out, more certain nformation would have been gained if the depth of uel bed and the blast velocity had been varied ndependently.

39. It may be pointed out that in tests 1 and 2 plant was really being tuned for the final low fuel test 3, and that test 4 corresponds to normal ice. We will only discuss the results of the last tests.

rature, blow-gas	—	—	860°	745°
rature, water-gas	—	·	650°	640°

It must be admitted that the measurement temperatures of the gases leaving the generator matter of no little difficulty, particularly in the of the blow-gas, when the blast velocity is high, blast period short, and the temperature of the ow-gas consequently high. Under these circum- ances the drop in temperature of the gas as it aves the generator must be very rapid, and error likely to arise through radiation from the thermo- nction, if it is not shielded, lag in the heat inter- ange between the gas and the thermojunction, and g in the heating of the thermojunction to a uniform mperature. All circumstances combine to increase he difference between the true and observed tem- peratures. Although the temperatures in the table bove really represent the maxima recorded, t is possible that they are still actually below he true temperature of the gases. The measure- ment of temperatures under the conditions which we are considering would repay further study. The quantity of primary air consumed per minute during the blow is in no case the result of direct observation, and there is no evidence which would enable us to differentiate between the carbon gasified as blow-gas, and the carbon consumed during clinkering.

It is therefore hardly worth making the laborious calculations involved in the compilation of a balance sheet. However, as the composition of the water-gas in both tests approaches to that of our standard we may use the formula to calculate the quantity of water-gas which the experiments should yield, supposing that the data tabulated are correct, and also supposing that allowances have to be made for incorrect temperature measurement, and for loss of carbon, reckoned as percentage loss on the carbon gasified as blow-gas. The following are the results of the calculations:—

TEST 3

Temperature of blow-gas	No loss	5% loss	10% loss
860° ..	72560 ..	70810 ..	69220
960° ..	67260 ..	65930 ..	64190

TEST 4

Temperature of blow-gas	No loss	5% loss	10% loss
745° ..	66680 ..	64880 ..	63150
845° ..	62770 ..	61130 ..	59400

Comparing these figures with item 5 in the previous table, it will be clear that the results of these tests would require considerable correction to make them balance. However, as they are strictly comparable they show quite clearly that the high CO_2/CO ratio in the blow-gas is a factor which makes for efficiency. While the conditions arrived at in Test 3 make for the higher gasification efficiency, they necessitate the slowing down of output, a matter which we are not now considering.

41. It has been shown that in studying the results of tests carried out on water-gas plants, balance sheets should be compiled showing, not merely that the total energy of the fuel is utilised, but also the relationship between the run and blow processes. If a balance is not then obtained it is clear that the experimental results are at fault. Study of the published results of experiments shows that they are subject to error partly owing to errors in estimating the sensible heats of the gases leaving the generator and partly to the fact that, as no allowance is made for loss of carbon, otherwise than as ash, clinker, etc., the amount of carbon supposed to be gasified as blow gas appears always to be too high. In order to extend our knowledge of the subject experiments should be carried out in which one factor only is varied at a time. Thus, by keeping a constant depth of fuel bed and changing the velocity of the blast, by maintaining a constant blast velocity and varying the depth of fuel bed, and by varying the size and quality of the coke when the other two factors were kept constant, we should obtain definite and valuable information as to the exact influence of these important factors. Measurement of the amount of primary air entering the plant would also serve as a valuable check on the consumption of carbon in the blow process.

THE POLYMERISATION OF DRYING OILS.

BY R. S. MORRELL, M.A., PH.D., F.I.C.

In a communication entitled "Ueber die sogenannte Polymerisation der trockenen Oele" (Z. angew. Chem., 1924, **37**, 729; B., 1924, 916), H. Wolff states that drying oils which have been thickened by heat, and the acids obtained therefrom are unimolecular in camphor solutions (Rast, Ber., 1923, **55**, 1051), and that the previous determinations in the case of the oils have given too high results, owing to the associating character of the solvents employed. I have been unable to find in Wolff's paper details of results obtained in the case of the thickened oils, although a table is given, showing that the acids obtained from the thickened oils are essentially unimolecular. The value of Wolff's conclusions rests entirely on the production of data obtained directly from the oils and not from the acids, and judgment must be reserved until these results are forthcoming. In the meantime it is advisable to point out that the results relating to the acids are not new. In 1915, after careful determination of the physical and chemical properties of thickened linseed oil (its acids and methyl esters) it was pointed out that the molecular weight of the two components of thickened linseed oil separated by means of acetone were 1788—2517 (oil insoluble in acetone) and 904—975 (oil soluble in acetone). The molecular weights were determined in benzol solution, and it is surprising that one part of the mixed glycerides (50%) should show great association, and the other part only very little, if benzol were considered as acting solely as a strongly associating solvent. Similar results were obtained with thickened poppy seed oil and China wood oil (J., 1915, 105).

Although the accuracy of the method using benzol as solvent for determining the degree of polymerisation has been criticised (J. Oil and Col. Chem. Ass., 1924, **7**, 153), it must be admitted that some form of polymerisation is indicated. In an earlier paper (1915) I pointed out the anomalous results that are obtained with the fatty acids, using benzol as solvent, and in the later communication (1924) I compared the results obtained by using glacial acetic acid with the stearic acid solvent method of M. Y. Seaton and G. B. Sawyer (J. Ind. Eng. Chem., 1916, **6**, 490; Biltz, Z. physikal. Chem., **19**, 385). Wolff's communication respecting the molecular weights of the acids from the thickened oils is not new. Both the acids and the methyl esters obtained from thickened linseed oil and China wood oil show only slight increases over the unimolecular state (J., 1918, 181 T), but on distillation *in vacuo* they give unimolecular distillates and multimolecular non-volatile residues (J., 1918, **37**, 181 T). It was shown that the polymerisation was not intra-molecular from the examination of the methyl esters obtained from thickened China wood oil. In my last communication (1924) the peculiar nature of the change is discussed in the light of evidence from the iodine values. It was pointed out that owing to the values obtained with varying times of contact with the Wijs reagent it was inadvisable to construct graphs representing the degree of polymerisation. The methyl esters from thickened China wood oil (insoluble in acetone) with a molecular weight in benzol of 393 showed iodine values rising from 138 ($1\frac{1}{2}$ hours' contact) to 168 (6 days' contact); China wood oil, heated for three hours at 205°, and insoluble in acetone, from 76·5 (1 hr. contact), rising to 150·8 (18 hours' contact); linseed oil, thickened at 260°, showed iodine values varying from 121 ($1\frac{1}{2}$ hours' contact) to 136 (20 hours' contact). Mention must be made of the increase in the molecular weight of oxidised α-elæostearic acid (in glacial acetic acid) and the ready gelation of oxidised linseed or China wood oil compared with the corresponding oxidised ethyl esters (Chem. Soc. Trans., 1918, **113**, 124; J. Oil and Colour Chem. Assoc., 1924, **7**, 159).

Until more is known of the process of gelation it is inadvisable to dismiss the conclusion that some form of molecular polymerisation occurs.

The composition of the oils plays an important part in their coagulation, either by heat or oxidation; moreover, the presence of the glyceryl group favours the setting of the oxidation product and the increase in viscosity when heat is applied. The setting is sensitive to the presence of small quantities of apparently inactive substances, which may or may not affect the rate of oxidation of the oil. An explanation from a colloid standpoint is always attractive, but it is not always satisfactory from a strictly chemical point of view. The influence of composition on the coagulation of oil systems does not admit an interpretation from a mere consideration of variable degrees of dispersion or sizes of aggregates. It is possible that the so-called polymerised oils are instances of special molecular complexes of dispersed material permeated by the dispersion medium which is of the same chemical composition (R. Zsigmondy, Z. physikal. Chem., 1921, **98**, 14). The thickening of drying oils, especially China wood oil, from experimental evidence appears to be a border case, whilst in linseed oil changes in the arrangement of the ethenoid linkages must not be overlooked.

The experiment described by Wolff (*loc. cit.*, p. 73) in connexion with changes in a China wood oil film illustrates "syneresis" or a possible lattice structure of linoxyn enclosing unoxidised oil. This occurs in most drying oil films in which the oxidation has been superficial. It has been shown by the present author that a surface of an oxidised China wood oil film is active and this activity is manifested long after the film is hardened.

l. XLIII., No. 52.] [December 26, 1924.

AMINATION OF THE BANDED CON-ITUENTS OF A DERBYSHIRE COAL.

BY H. D. GREENWOOD, M.SC., A.I.C.

nomenclature originally introduced by Stopes Wheeler to distinguish between the constituents banded coal has been generally adopted, and the racteristics of the four ingredients—fusain, durain, rain, and vitrain—are well known. The proper- of these bands from a number of coals have been estigated by several workers.

ideswell and Wheeler (Chem. Soc. Trans., 1919, , 619) made a detailed analysis of a New Ham- d coal, together with a distillation *in vacuo* at °; Lessing (*ibid.*, 1920, 117, 247—256) extended se investigations to laboratory distillation tests 00° and 900°, and also to analyses of the ash from different bands. Analyses of the bands from the p Hard Seam, E. Kirby Colliery, are given by ranov and Francis (Fuel, 1922, 1, 219).

impression gathered from a survey of these ilts is that there is a general gradation of certain perties of the four constituents in the order, rain, clarain, durain, and fusain.

he ultimate analyses show a gradual rise in carbon l fall in oxygen content, and the above order ears to hold also for the other properties investi- ed.

e results given by Tideswell and Wheeler may d as an example :—

	Vitrain	Clarain	Durain	Fusain	
	%	%	%	%	
l.. .	12·6	10·2	6·5	3·9

..	13·0	13 4	11·8	9·7	
per g. ..	184 c.c.	206 c.c.	194 c.c.	—	(Lessing)

vestigators agree in finding differences in the properties. The vitrain and clarain give ollen-coke, whereas the durain undergoes ly no change in volume, and fusain is entirely of coking properties.

he following paper are recorded the results of mination of the banded constituents of a Derby- coal from Flockton and Parkgate seams of ngton Colliery. The examination is divided two sections :—

Analyses and distillation in small silica retort.

., Examination of the resulting cokes.

Experimental.

The coal samples were obtained by picking lumps coal from truck deliveries from the colliery, these ng selected so as to show their banding clearly, l the bands then separated by hand.

The durain and clarain, which formed well-defined nds, were easily distinguished and separated, hough care was necessary that no thin laminæ of durain were present in the clarain bands, and *vice versa*. The detection and separation of the vitrain presented greater difficulty.

On casual examination the clarain and vitrain were very similar, but the latter had a more brilliant surface lustre which was not banded as in the clarain. The vitrain, which was almost vitreous in texture, when broken into small fragments showed a distinct conchoidal fracture, whilst the clarain split into parallel laminæ.

As the vitrain only occurred to a small extent in the coal and in very thin bands, its separation from the matrix was difficult, and it was only after the examination of many samples that the vitrain was found in bands sufficiently large to allow of its separation.

The samples thus obtained were ground to pass a sieve of 60 meshes to the inch, and stored in air-tight bottles.

Proximate analyses of each were carried out according to the methods of the American Chemical Society.

Distillation tests.—The distillation at 900° was carried out in a small silica retort, heated by a specially designed gas furnace. The furnace was so constructed that the front 4 inches of the retort could be raised to the distillation temperature before heating the rear portion containing the coal, providing a region where the volatile matter evolved during the early stages of the distillation might be superheated and thus give some approximation to the conditions prevalent in a horizontal retort in practice.

Ten grams of coal were placed in the rear portion of the retort in order that the volume of free space immediately above the coal might be the same in each experiment. The liquid products were collected in a water-cooled U-tube, and the gas passed, *via* an acid bubbler, to a gasholder, which was filled with water and glycerin. The pressure in the apparatus was maintained uniform throughout the distillation by the constant-level device described in the Fuel Research Board Report, No. 1.

The retort and condenser were weighed before and after the experiment to determine the yield of coke and liquid products. The tar was dissolved in chloroform and the liquor separated and measured; the tar adhering to the side tube of the retort was burnt off and the loss in weight recorded and added to the bulk of the tar. The gas analyses were carried out in a modified Orsat apparatus and the nitrogen was determined by direct combustion over copper oxide.

Discussion of results.—The proximate analyses (Table I.) of the clarain and vitrain were very similar, and the low ash content of all except the fusain was noteworthy. The gradation of properties which has been observed with other coals (*loc. cit.*) is not so well marked in the present instance.

The moisture content follows the order observed with other coals, but the durain has a considerably higher volatile content than the other bands, and the ash is practically the same for each band, excluding the fusain.

TABLE I.

	Fusain.	Durain.	Clarain.	Vitrain.	Eckington coal.
Density . .	1·4·4	1·310	1·317	1·312	
Proximate analysis—					
Moisture	1·60%	2·61%	2·80%	3·30%	2·5%
Volatile (ash- and moisture-free).	21·3	39·2	36·2	35·3	34·6
Fixed carbon .	78·7	60·8	63·7	64·6	59·1
Ash . . .	10·08	2·1	2·1	2·0	7·1

The above figures are not the results of an isolated test, similar results having been obtained with many samples.

The fusain must be considered in a class apart, since its properties differed greatly from those of the other bands. It is marked by a high ash and low moisture and volatile content, in which respect it is in agreement with the analyses of other observers on different coals.

The deliveries of this coal sampled from wagons in the ordinary way contain from 9 to 13% of ash, showing the large proportion of adventitious matter.

Results of distillation tests.—The three coking bands yielded similar results on distillation at 900°, as might be anticipated from the proximate analyses.

The yield of gas was greatest with the vitrain and least with the durain, but for the tar yields this order was reversed.

In each case the total volatile matter evolved was less than in the crucible test (proximate analysis), due probably to the secondary decomposition of the tar etc., with the formation of carbon on the walls of the retort.

The composition of the gas was similar for the three coking bands and calls for no comment.

With the fusain, the tar and gas yields were much lower and the gas was poorer in quality, containing 16·5% of methane and 60·6% of hydrogen, compared with 28·5% and 49% respectively in the gas from the clarain (see Table V.).

TABLE II.

Results of distillation tests.

	Coal as sampled.					Ash- and moisture-free coal.				
Coal.	Coke, %	Tar, %	Liquor, %	Gas c.c. 10 g.	Total volatile.	Coke, %	Tar, %	Liquor, %	Gas c.c./10 g	Total volatile.
Vitrain .	65·7	7·7	8·0	3465	34·3	67·3	8·1	4·9	3660	35·2
Clarain .	65·4	8·0	7·5	3390	34·6	66·5	10·3	5·3	3560	33·4
Durain .	62·3	12·1	5·9	3280	37·1	62·8	12·7	3·4	3440	36·3
Fusain	80·3	3·6	4·8	2400	19·7	79·5	4·1	3·6	2710	21·3
Eckington (av. sample) . .	66·8	8·9	7·5	3100	33·3	64·6	10·2	5·7	3450	34·6

In Table II. are also recorded the results of an average test of Eckington coal as sampled in the ordinary way; the relatively high tar and low gas yields will be noted.

Examination of the cokes.

The cokes, after cooling and weighing, were extracted from the retort and the real and apparent specific gravities determined by the methods described by Greenwood and Cobb (J., 1922, 181—183 T).

In order that the free space available for expan above the coal might be the same in each test, was taken that the coal occupied the same portio the retort in each experiment.

The specific gravities of the original coal and cokes are collected in Table III., and in Table IV calculated the changes in volume which take plac the coking process starting with 100 g. of coal.

TABLE III.

Physical properties of cokes.

	Fusain.	Durain.	Clarain.	Vit
Real specific gravity	1·980	1·877	1·880	1·
Apparent specific gravity . .	1·980	0·980	0·600	0·
Percentage porosity	Nil.	49·8%	68·0%	70·

TABLE IV.

Changes in volume on coking in silica retort.

	Weight, g.	Volume of coal c.c. A	Total Volume of coke c.c. B	Change in volume c.c. (A B)	Volume of coke material c.c. C	Dec in vo from c. (A-
Fusain—						
Original coal .	100·0	68·8	40·2	−28·6	40·2	−2
After coking at 900°	79·5			=−41·5%		=−4
Durain—						
Original coal . .	100·0	71·4	61·2	−10·2	32·0	−3
After coking at 900°	60·0			=−14·2%		=−5
Clarain—						
Original coal . .	100·0	77·0	104·5	+27·5	33·3	−4
After coking at 900°	62·7			=+35·7%		=−5
Vitrain—						
Original coal . .	100·0	76·1	115·0	+38·9	33·8	−4
After coking at 900°	63·6			=+51·1%		=−5

As is usual, the fusain was entirely devoid coking properties, and the residue consisted of greyish, non-porous powder with a relatively h specific gravity, as the coal contracted 48·5% of original volume on carbonisation.

The durain, which may be regarded as int mediate in its properties between the str coking clarain and non-coking fusain, po sufficient agglomerant to bind the particles t and form a dense, hard coke; the decr volume was only 14·2%, as compared with with the fusain, the difference constituting th space in the durain coke. The material reta original shape to a large extent, and showed n of inter-fusion of the particles. This prop clearly demonstrated by coking a small cube coal, when a similar cube of coke is formed with tically no change in volume.

Both the clarain and vitrain gave highly sw cokes, especially the vitrain, which showed a te dency to "mushroom" formation. To the ey these cokes appeared very similar, but from Table I it will be seen that the vitrain expanded 51·5% its original volume, compared with 35·7% for th clarain. These cokes were completely fused an covered with a film of bright retort carbon

The low specific gravity of these cokes em phasises the expansion which has taken place, th figure 0·981 for the durain being comparable with th average figures for gas and oven coke. The decrea in volume of the coke material by loss of volati matter was similar for the three coking bands, an in marked contrast to the differences in volume o the coke material together with the pore spaces.

The centre of both the clarain and vitrain cokes
s composed of relatively large, and the periphery
small, cells, showing that the expansion had
ust the coal against the sides of the retort, where
pressure of the expanding material prevented
formation of large cells.

TABLE V.

Gas analysis.

	H_2S & CO_2	O_2	C_nH_m	CO	H_2	CH_4	N_2
ngton coal	2·7	1·2	3·8	7·0	49·0	27·7	8·6

ain	2·0	1·3	4·0	6·4	49·0	28·5	8·8
ain	1·9	1·3	3·9	6·3	49·5	29·0	8·1
On air-free basis.							
ngton coal	2·0	--	4·0	7·4	53·1	29·4	2·0
ain	2·7	—	3·1	8·9	64·2	17·4	3·5
ain	2·03	--	4·3	7·5	54·3	28·1	3·77
ain	2·10	--	4·2	7·2	52·2	30·3	3·94
ain	2·0	--	4·1	7·06	52·7	30·9	3·24

When coal is carbonised in small samples and
ler conditions which allow free expansion, the
parent specific gravity of the resulting coke is
siderably less than when the coal is coked in bulk,
superincumbent weight of the charge and the
raining influence of the retort walls then prevent-
excessive expansion.

Considering these results from the standpoint of
bonisation practice, it may be anticipated that
ls containing a large proportion of clarain and
rain will show a considerable expansion on coking,
being tempered by the durain present.

Where coals are carbonised in the rough, as in
id-stoked horizontal retorts, the different expan-
s of the bands should result in a want of uni-
nity and a consequently weaker coke.

The greater the degree of subdivision of the coal
more uniform should be the resulting coke, and
derable scope is thus offered for the blending of
ontaining different proportions of banded
ents.

Summary.

he banded constituents, durain, clarain,
and fusain, of a Derbyshire coal (Eckington
) have been separated and subjected to
te analyses and distillation tests on a labora-
le. The porosity and specific gravity of the
rom these tests have also been determined.

The fusain may be considered in a class apart
is characterised by low volatile and high ash
; it was further entirely devoid of coking
ies.

The durain, clarain, and vitrain showed much
ty in certain properties, but the gradation
above order which has been recorded for other
oc. cit.) was hardly appreciable.

The vitrain and clarain gave highly swollen
but the durain showed very little change in
, and even a slight decrease in volume on
king.

(5) The real specific gravity was practically identi-
in all the three cokes, but owing to the different
gree of expansion on coking the apparent specific
vity was greatest with the vitrain and least with
durain.

The author wishes to express his thanks to Mr. F. G. Shaw, Engineer and Manager of the Burton Corporation Gas Dept., for permission to publish these results.

NOTES ON ALLOY METALS USED IN ALLOY STEELS.*

BY JULIUS L. F. VOGEL.

For the purpose of this paper steel will be regarded as iron containing small percentages of carbon and silicon as essential constituents, whilst alloy steels will be regarded as containing in addition definitely predetermined quantities of one or more other metals.

It should be borne in mind in connexion with steel of every kind that the manufacturers and consumers are interested solely in its physical qualities. For them chemical analysis is merely a means of insuring uniformity in successive heats and freedom from excess of impurities which are known in practice to affect the physical qualities adversely.

To realise the part played by the different alloy metals it is necessary to visualise to some extent the structure of alloy steels, and for this purpose a study of a recent paper by M. Grossmann and E. Bain† is useful, as it summarises the accumulated knowledge of many workers in this branch of metallurgy. The paper deals with an investigation into the nature of high-speed steel which contains tungsten, chromium, and vanadium in addition to iron, carbon, and silicon. Its properties are great tensile strength to withstand the enormous strain of heavy and fast cutting without breakage or distortion, together with great hardness, which is maintained even at high temperatures. The cutting edge of a tool made from such steel will not be softened and become blunt, even when it is heated to a visible red by the friction and strain of taking heavy cuts at high speed.

The conclusions arrived at in this and other papers are, briefly :—

1. That a carbon steel is a definite crystalline structure in which the size, chemical composition and disposition of the crystals are regulated by the quantity of carbon, the work under the hammer and rolls, and the heat treatment.
2. That in high-speed steel certain of the additional metals form true alloys with the iron and carbon, and thereby produce a matrix of greater tensile strength than carbon steel, and that other of the alloy metals for the most part form carbides which are very hard and refractory.
3. That by suitable preparation, mechanical and heat treatment, the finished steel can be produced so as to consist of the matrix through which the carbide crystals are evenly distributed.
4. That a further use of some of the added metals is to combine with oxygen or nitrogen in the molten steel and carry these elements into the slag.

* Read at a meeting of the Liverpool Section on Nov. 21, 1924.
† Iron and Steel Institute, September, 1924.

With this conception of the structure of an alloy steel it is interesting next to study a list of the metals which are thus utilised, and at the same time to compare them with others which, if present in excessive quantities, are found to be deleterious.

A very great number of elements may be detected by a complete analysis of alloy steels, but attention is only drawn to those which are added or avoided intentionally. Further, it must be borne in mind that scientific investigation is in progress in many laboratories and factories where alloy steels of every kind are under examination. In consequence, certain of the elements tabulated are still only under observation and not in commercial use to any extent, but these are included for the purpose of comparing their properties with those of elements of already proved utility.

The tables are arranged in the order of the chemical groups, but no evidence can be deduced from the classification, as the same groups are found to include both useful and deleterious elements, as, for instance, chromium and sulphur.

Table of the elements employed in the manufacture of alloy steels.

	Sp. gr.	m. p.
A. *Useful Elements.*		
Titanium	4·87	2500°
Zirconium	6·40	1800°
Carbon	2·3	4000°
"	3·5	—
Silicon	2·3	1200°
Vanadium	5·5	1680°
Chromium	6·92	1550°
Molybdenum	9·01	2110°
Tungsten	18·7	2800°
Uranium	18·7	1800°
Manganese	8·0	1240°
Iron	7·86	1520°
Cobalt	8·8	1490°
Nickel	8·8	1452°
B. *Employed as a reagent.*		
Aluminium	2·56	654°
C. *Considered deleterious or at the best of no value to alloy steels.*		
Copper*	8·95	1084°
Tin	7·3	232°
Antimony	6·8	630°
Bismuth	9·7	270°
Phosphorus	1·83	44°
Arsenic†	5·73	—
Sulphur	2·07	115°

* Copper is said to be utilised in some steels, but generally it is specified as deleterious in ferro alloys for steel making.

† Volatilises without fusing.

A study of this table does not convey much information.

The most noticeable point in the useful alloy metals is their high melting point. Manganese alone melts substantially below iron. Of the others, cobalt, nickel, and chromium have melting points approximating to that of iron, whilst the others have very high melting points.

Now manganese, cobalt, nickel, and chromium very largely enter into the steel as a true alloy, and impart to it definite physical characteristics, whilst the metals of high melting point tend more to appear in the finished steel as complex carbides held in the matrix.

These are generalised statements and only to be applied cautiously, but they may indicate to some extent the effects of different elements on the steel.

Aluminium occupies a peculiar position. At the temperature of molten steel it is readily oxidised, and if added to a melt containing ferrous oxide effectively deoxidises the bath. Hence it is used "doctor" over-oxidised or boiling metal, ingots fro which would be filled with gas bubbles. The al minium oxide is light and passes readily to the sl floating on the surface. Over-treatment with alu minium, which results in some of the metal remainir unoxidised and in admixture with the steel, is foun to be bad for certain classes of steel. Hence cautic is desirable in adding what is, for its legitima purpose, a useful reagent.

Turning to the deleterious impurities, phosphoru arsenic, and sulphur are all well known to affe carbon steel adversely, and equally so alloy stee The proportion of these must in consequence be ke very low in ferro alloys or metals used in making all steel.

Tin is objected to and also copper, for reasons wh are not specifically stated. The importance restriction of these metals lies in the fact that wolfra the raw material for making tungsten, is alwa associated with tin ore, and copper is often pres in molybdenite and must be watched for in a minium used for thermit reduction.

Thus, the problem facing makers of ferro allo and alloy metals for steel makers may be brie summarised by saying that the products they supp must contain the desired metals within comparativel narrow limits, and that they must be free fro any deleterious or even doubtful impurities. Fur ther, the maker of the ferro alloys must be conten to realise that his product will be judged more by th physical properties of the steel produced than by th assay of the ferro alloys themselves. The only sa course is to keep the products as free as possible fro the impurities he wishes to avoid. In the first plac therefore, he buys the ores he uses as raw mat on very strict specifications. It is not, of always possible to obtain all necessary supp the highest quality, but prices are redu direct ratio to impurities. Broadly speakin ferro alloys such as ferrotungsten, ferrochron ferromolybdenum, which are reduced directl the ores by electric furnace or by thermit pro call for the purest raw materials, since the poss of eliminating impurities in the course of manuf is very limited.

The pure metals such as nickel, cobalt, tun or chromium made by isolating the oxides, ca produced from considerably less pure raw mate since the impurities can be eliminated in proce manufacture whether by wet or dry methods.

It is obvious from a study of the table that number of elements which definitely modify physical qualities of steel is very great. Since vary quantities of each element have marked effects, three, four, or more may be utilised in different rat to one another, it is obvious that the number combinations is almost infinite.

The purely commercial problem facing makers of alloy steels, viz., that of complying with certa physical tests, is in itself complicated. Alloy ste to comply with the specification physically may be obtainable by several different mixtures, and the c st

raw materials is an important consideration. For tance, if 5s. worth of tungsten gives the same ults as 10s. worth of molybdenum in a high-speed el, it is obvious which metal will be used commer- lly. Thus, it is a problem to which there may many solutions, and fluctuation in price of raw aterials may vary the answer from time to time hen costs are considered.

The demand for a special alloy metal which is are will, as a rule, create a supply sooner or later, llowed generally by reduced cost. For instance, fore the war the ores of tungsten were compara- ely scarce, but the enormous war demand resulted the discovery of entirely fresh sources of supply d consequent reduced prices.

No attempt will be made here to deal in detail with manufacture or origin of the various metals under cussion, but a few words on these subjects may be ful.

itanium.—This metal is used in alloy steels, for most part as a scavenger to deoxidise finally the al before teeming, and for this purpose it is added he ladle. The quantity employed is only sufficient this purpose, and none of the metal is to be found the finished steel.

Numerous claims have been made for its efficacy an ingredient of steel, and it can be classed as er investigation rather than as a metal employed mercially by steel makers. To the extent that s used, it is rather in castings than in steel for ing or forging. The ferrotitanium is prepared electric furnace or thermit methods from rutile, ineral which is by no means rare.

irconium is still in the experimental stage, and e is no commercial demand in this country. Many l makers who have experimented with it have d that the metal cannot be traced in the steel, t it appears to have gone entirely into the slag. very high melting point, and strong affinity en, together with a low specific gravity, so y no means improbable.

supplies of zirconium ores could be obtained, oxide is in some demand as a refractory, separation from silica presents a somewhat un problem commercially, and restricts its igh cost.

fractory purposes high zirconium and low necessary, and these points are those chiefly tched in examining the ore.

and *silicon* need not be discussed as they the same sense alloy elements, their presence eing fundamental and the subject of adjust- her than of addition.

ium is an alloy metal that has come largely during the last twenty years. It is one of interesting of the series. Its effects on the properties of steel are very marked and so as an addition to steel containing other metals.

he chief sources of vanadium are the sulphide of Peru and the lead vanadate mined in Central ca. Vanadium is also found in association with nium and in ashes from Peruvian bituminous coal.

The problem of smelting vanadium for use by steel makers is not altogether simple. In the first place the actual product they require is ferrovanadium, containing limited percentages of silicon and carbon and 35—50% of vanadium. A higher vanadium content gives an alloy too low in specific gravity and not sufficiently fusible.

Rich sulphide ores containing 20—30% as sulphide can be roasted to oxide and reduced in admixture with iron oxide by aluminium. This process was the one chiefly in use for some years when the Peruvian mines were producing large quantities of rich sulphide. The cost of production in this way was comparatively low and the product satisfactory, although somewhat higher in silicon than now specified by many consumers.

The reduction by aluminium is subject to sub- stantial loss in the alumina slag, and over a period this amounts to a very considerable stock. B. D. Saklatwalla worked out the recovery of the vanadium from these slags in electric furnaces, and supplied large quantities during the war, but the quality is considerably lower than the original aluminothermic product.

The recovery of vanadium from lead vanadates in- volves quite different methods. The minerals contain 10—20% V_2O_5 and varying quantities of lead, zinc, and copper. In many cases there is a very substan- tial quantity of phosphorus, which must be eliminated. Vanadium oxides, as is well known, are almost equally soluble in mineral acid and alkaline reagents. Further, in wet methods of extraction vanadic oxide precipi- tated by careful neutralisation brings down with it oxides of other metals, generally as slimy, unfilterable precipitates.

In practice, therefore, it is found that the different ores of vanadium, although very similar in composi tion, require special treatment for the production of vanadic oxide and ferrovanadium, and that each ore must be studied as a separate problem. For sale and purchase of vanadium ores a complete analysis is desirable and almost essential. Special attention must be paid to accurate determination of the phos- phorus.

Chromium is very largely used for alloying with steel. It increases the tensile strength and hardness, and it is employed to a considerable extent as a third or fourth ingredient in alloy steels containing a number of alloy metals. Ferrochrome is sold in various grades, according to the carbon contents, which vary between commercially carbon-free (under 0·1%) and 8—10%, and prices rise rapidly as the carbon contents fall.

Practically the whole production is made in electric furnaces smelting chromite ores containing 48—52% Cr_2O_3, together with iron oxide, magnesia, and silica. Impurities such as sulphur and phosphorus are not usually present in large proportions in the ores, which are mainly produced in Rhodesia, New Cale- donia, South-East Europe, and America, though there are sources of supply in many countries.

Chromium is specially interesting to-day as an alloy metal, since it is the main constituent, other than iron, of stainless steel and iron, which contain 10—20%

Cr. The reason for the high resistance of these alloys to corrosion is not yet satisfactorily explained, but generally speaking they seem to have in an exaggerated form the well-known properties of iron in a passive state. For ferrochrome production silica is frequently specified within certain limits, and in consequence the assay of the minerals must be watched for this as well as for magnesia, iron, sulphur, phosphorus, and arsenic. The use of chromite ore without treatment as a refractory is, of course, well known, and in this case experience is largely a guide to the relative values of minerals of different origin.

Molybdenum has very pronounced effects on the physical qualities of steel. It shares with tungsten the property of imparting red-hardness, or hardness at abnormally high temperatures, and for this purpose can be used as a constituent of high-speed tool steels. Its effects in this direction are more pronounced than those of tungsten, and the percentage required is only about one-fourth to one-third of the tungsten used in making high-speed tungsten steels. Its disadvantages are first cost, which is more than proportionally higher than that of tungsten, and the volatile nature of molybdic oxide which tends to reduce the amount of the metal alloyed with the steel, and in particular makes it difficult to insure uniformity of molybdenum contents in successive heats.

On the other hand, molybdenum is utilised to a considerable extent for other classes of steel to increase hardness and strength, and it is required in some specifications for armour plate.

The mineral used for the most part is molybdenite, which is mined in several places, notably Canada, Norway, and Australia. It is not a simple mining proposition, as the values are generally very patchy and concentration is difficult, but has been solved to a considerable extent by flotation. Lump ore is very difficult to grind and water concentration involves prohibitive losses in float mineral.

Ferromolybdenum is produced directly from the sulphide in an electric furnace, or by thermit methods from the calcined ore. There are two recognised grades containing respectively 1% of carbon and upwards, and carbon-free, the molybdenum varying between 60 and 80%. Copper is frequently present in the ore, and a maximum of 0·25—0·75% Cu is often specified in the alloy. This, therefore, must be watched for carefully in assays of the mineral, as also phosphorus, since large quantities of molybdic acid are used for the rapid determination of phosphorus in steel.

Tungsten has been used for half a century or more to impart red-hardness to tool steel. Starting with 3—4% introduced by adding pure tungsten ore into the steel crucible, it has gradually risen to nearly 20% in the most efficient tungsten-chromium-vanadium high-speed steel. It is also used for permanent magnet steel in small quantities (2—4%).

The use of tungsten for incandescence electric lamp filaments and for terminals in electro-magneto coils is well known, but absorbs only a comparatively small tonnage.

The main use is for tool steel, and for this pur[illegible] it is employed either in the form of powder (98—[illegible] W) or ferrotungsten (80—85% W). Powde[illegible] prepared by isolating tungsten trioxide by an alka[illegible] melt, lixiviation, precipitation by mineral acid, [illegible] reduction of the trioxide thus obtained. Fe[illegible] tungsten is made by direct smelting of the min[illegible] either electrically or by thermit methods.

The ores, mainly iron tungstate (wolfram) [illegible] scheelite (calcium tungstate), are very widely [illegible] tributed and generally associated with tin. Chi[illegible] Burma, Malaya, Australia, and the United States [illegible] the chief producers, but supplies collected during [illegible] war and remaining as unconsumed stocks have co[illegible] pletely upset the mining of tungsten ores, and for [illegible] most part there is little or no production at prese[illegible] except in conjunction with tin. Standard wolfr[illegible] contains 65% WO_3 and upwards and less th[illegible] 1—1½% Sn, but consumers when they can pick [illegible] choose, reject ores containing much sulphur, arse[illegible] and copper. Further, for direct smelting the relat[illegible] percentages of iron and manganese in wolfram [illegible] important, as ferrotungsten is generally specified [illegible] contain a certain maximum of manganese.

Uranium is one of the metals on probation as [illegible] alloy in steel. Up to the present it has only be[illegible] tried experimentally, and the results claimed h[illegible] not led to any general commercial use.

It has been produced as a by-product in reco[illegible] radium from pitchblende. The oxide is isolat[illegible] the reduction to metal or ferro alloy involve[illegible] siderable difficulties, since great heat as w[illegible] thermit reagents are required. It is done, the[illegible] in an electric furnace with aluminium, and in [illegible] ducing or neutral atmosphere.

The ore, formerly mined to some extent in [illegible] rado, Portugal, Austria, Cornwall, and else[illegible] now comes almost entirely from the Be[illegible]an [illegible] where large and cheaply worked deposits hav[illegible] discovered.

Manganese is an indispensable alloy meta[illegible] in small quantities, but special steel co[illegible] 14—16% of manganese is utilised for many pu[illegible] where a very hard and tough metal is required. [illegible] alloy is generally cast and ground, as it is di[illegible] to machine. Rolls, jaws for stone crushers, tra[illegible] points and crossings, and many other useful pr[illegible] are made from it. The ore is found in many p[illegible] and is the subject of a great deal of literature, so tha[illegible] even a brief reference to the metallurgy and assay [illegible] unnecessary.

Cobalt is now utilised to a considerable extent [illegible] steel for permanent magnets and other uses. It i[illegible] bought as pure metal reduced from the oxide int[illegible] cubes or shot. The bulk supply comes from Canada where large bodies of ore are mined, primarily fo[illegible] their high silver contents. The metallurgy follows orthodox lines of solution, purification of solutions, and precipitation of cobalt oxide. There is, too, a steady consumption of cobalt oxide in the ceramic industry.

Nickel has been employed for a long time as a[illegible] alloy metal in steel. Its utilisation can be traced in

allel with the battle between defensive armour armour-piercing projectiles. Nickel steel and ome-nickel steel are standard products for use re high tensile qualities are required. The chief ducing countries are Canada and New Caledonia, ough many other deposits are known.

he metallurgy is complicated and interesting, as volves two very different principles. The Mond ess of volatilising nickel carbonyl and decom- ing it at a higher temperature is opposed to elec- ytic purification of crude smelted metal. These esses and many others are described in technical lications and need no further reference.

t is not claimed that these notes have dealt austively with the elements of use in or detri- ntal to alloy steels. Their main object is to cate the vast field that has been opened up in industry, which by its very nature calls for the operation of chemists at every stage. The steel- ks laboratory can no longer concern itself only h carbon determinations and tests for phosphorus. here are still many blank pages in the chemical ly of alloy steels, and not the least of these is the estigation of rapid and accurate methods for the ermination of different elements in admixture h others.

he steel-maker's verdict is based eventually on sical tests, and the chemist and alloy maker are called upon to account for troubles which may e within their province. Nevertheless, for n production to meet physical tests, uniform al composition is essential, and those deal- th the assay of ores and ferro alloys, and kers of those special metals, must exercise ing care if they are to avoid introducing al troubles into the manufacture of alloy To this end rapid and accurate methods of s are essential, especially when they can be dised for use by buyer and seller.

oved methods of preparing the alloy metals o alloys, and the exact influence of impurities physical qualities of steel, are also subjects ich chemical investigation can materially the production of alloy steels.

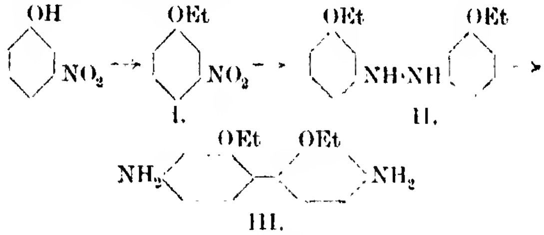
PARATION OF ISODIPHENETIDINE.

OHN REGINALD HARVEY WHISTON, M.A., B.SC.

During the course of another investigation it came necessary to prepare *m*-nitrophenetole, and was thought to be of interest to convert this bstance into the corresponding diphenetidine, as e latter does not appear to be described in the erature. It is also of interest in order to test the neral rule that only homologues of benzidine ntaining substituents in the ortho position to the nino groups yield azo dyestuffs substantive to otton. *iso*Diphenetidine is no exception to this rule, on tetrazotising and coupling it only yields dye- uffs substantive to cotton when coupled with such ds as S-acid (8-amino-α-naphthol-5-sulphonic acid) hich themselves appear to confer the property of rming substantive dyestuffs for cotton.

Experimental.

The reaction scheme evolved for the preparation of *iso*diphenetidine was:—



Preparation of m-*nitrophenetole* (I.).—A solution of 139 g. of *m*-nitrophenol (prepared by diazotising *m*-nitroaniline in sulphuric acid solution and decomposing the diazo compound by boiling) in 250 c.c. of 20% sodium hydroxide solution was heated to gentle boiling under reflux, and 215 g. of ethyl *p*-toluenesulphonate (recrystallised from methylated spirit) added in quantities of about 50 g. at a time at 10—15 minute intervals. When all had been added the reaction mixture was refluxed 6—7 hours, a further 40 c.c. of 20% sodium hydroxide solution added, and the nitrophenetol distilled off in steam. Yield 150 g. (90% of theory); m.p. 33°.

Preparation of mm'-*diethoxyhydrazobenzene* (II.). 33·4 g. of *m*-nitrophenetole were added to a solution of 25 c.c. of alcohol (92%), 50 g. of sodium hydroxide, and 150 c.c. of water contained in a flask fitted with a stirrer and reflux condenser. With vigorous stirring, 60 g. of zinc dust (90%) were added in small portions at a time so that the reaction mixture kept gently boiling. It was necessary to heat the flask on the water bath during the addition of the last 10—15 g. of zinc dust. 100 c.c. of water were then added, and the reaction mixture was left overnight. The pale yellow solid which had formed on the top was separated from the zinc residues by pouring on to a sieve (40-mesh) and washing with water. It was then ground up with dilute hydrochloric acid, filtered, washed with water, and air-dried. After recrystallisation from light petroleum (b.p. 40°—60°) the hydrazo compound was obtained in almost pure white crystals in yield of about 75% of theory; m.p. 86°. (Found N = 10·2%: $C_{16}H_{20}O_2N_2$ requires N = 10·3%.)

Conversion of mm'-*diethoxyhydrazobenzene into* iso-*diphenetidine* (III.).—This conversion does not proceed so smoothly as the conversion of the simple hydrazobenzene into benzidine. The following method was found to give the best results: 34 g. of the hydrazo compound were ground with 100 c.c. of cold hydrochloric acid (33%), the mixture was heated for 15 minutes on the water bath, and finally boiled gently for 15 minutes. On adding hot water (350 c.c.) almost complete solution took place. After filtering hot, the filtrate was made alkaline by the addition of dilute sodium hydroxide solution, and the free base, which separated as an oil, extracted with benzene. The benzene extract was boiled with charcoal and filtered, and the benzene distilled off under diminished pressure. The residue set to a somewhat sticky, crystalline mass, and the pure *iso*-

diphenetidine was obtained from this by two recrystallisations from dilute alcohol, the final yield being 12·5 g. (37% of theory); m.p. 109°. (Found C = 70·6%, H = 7·2%, N = 10·2%; $C_{16}H_{20}O_2N_2$ requires C = 70·6%, H = 7·3%, N = 10·3%.)

Summary.

*iso*Diphenetidine (m.p. 109°) has been prepared from *m*-nitrophenol. It does not yield azo dyestuffs which are substantive to cotton.

The bulk of the above work was carried out in the Dyson Perrins Laboratory, Oxford, and the author owes his thanks to Prof. W. H. Perkin for the kindly interest he took in the work, to Mr. F. Hall for making the necessary analyses, and to The British Dyestuffs Corporation and the Commandant, Artillery College, for permission to publish these results.

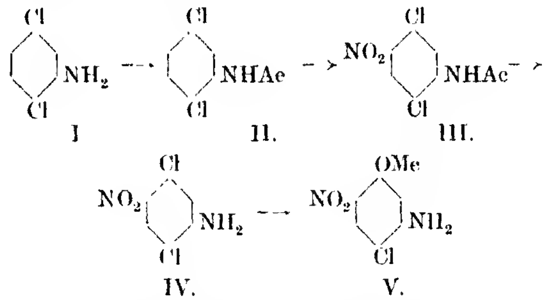
THE PREPARATION OF 4-CHLORO-6-NITRO-*m*-ANISIDINE.

BY JOHN REGINALD HARVEY WHISTON, M.A., B.SC.

This compound is mentioned in G.P. 216,417 (Friedländer, IX., 419), but no details as to its preparation or properties are given. As it was required in connexion with some other work, its preparation was attempted from 2.5-dichloroaniline (I.) by the following reaction scheme:—



The preparation of 2.5-dichloro-*p*-nitroaniline (IV.) is mentioned by Noelting and Kopp (Ber., 38, 3514), but their method has been considerably modified, and very good overall yields of 4-chloro-6-nitro-*m*-anisidine have been obtained.

Experimental.

To 20·4 g. of 2.5-dichloroacetanilide (II.) (prepared from 2.5-dichloroaniline by the usual method of treatment with acetic anhydride) dissolved at 45° in 80 c.c. of sulphuric acid (96%) and cooled to 5°, a mixture of 12 g. of nitric acid (66%) and 60 g. of sulphuric acid (96%) was slowly added, with stirring, the temperature rising to 10°. The mixture was allowed to stand for 15 minutes at room temperature, poured on ice, the precipitated nitro compound filtered off, washed with water, and pressed. Without drying, it was heated for 2 hours on the water bath with 150 c.c. of sodium hydroxide solution (8%). After cooling and adding water, the yellow dichloronitroaniline (IV.) was filtered off, well washed with water, and dried. Yield 19·5 g. (94% of theory); 152°—153°.

Preparation of 4-chloro-6-nitro-m-anisidine (V 10·4 g. of 2.5-dichloro-*p*-nitroaniline were refl for 8 hours on the water bath with 50 c.c. of me alcohol and 4 g. of sodium hydroxide. After coo the reddish-yellow product was filtered off, wa with water, and dried. Yield 8·7 g. (85% of theo m.p. 154°—155°. On recrystallisation from ben it forms pale yellow, needle-shaped crystals of 156°. (Found C = 41·3%, H = 3·5%; $C_7H_7O_3$ requires C = 41·5%, H = 3·5%.)

Summary.

4-Chloro-6-nitro-*m*-anisidine has been prep from 2.5-dichloroaniline. It forms pale yel needle-shaped crystals, m.p. 156°.

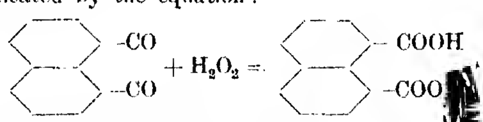
The author wishes to thank Prof. R. Robinson his interest in this investigation, and also The Br Dyestuffs Corporation and the Commandant, Arti College, for permission to publish the results.

Artillery College, Woolwich.

THE PREPARATION OF NAPHTHALIC A BY OXIDATION OF ACENAPHTHAQUINONE.

BY JOHN REGINALD HARVEY WHISTON, M.A., B

Although naphthalic acid is usually obtained a by-product in the preparation of acenaphthaquinc it was thought to be of interest to determine whet it was possible to convert acenaphthaquinone naphthalic acid by means of hydrogen peroxide indicated by the equation:—



This reaction has been found to proceed very sm an almost quantitative yield of the acid bei tained.

Experimental.

192 g. of a paste of acenaphthaquinone (25% stirred to a smooth suspension with 100 c.c. of hydroxide solution (25%) and 200 c.c. of After heating to 40°, a solution of hydrogen pe containing about 15% excess of hydrogen pe was slowly added, the temperature being raise boiling during the addition. The acenaphthaquinc was rapidly converted into naphthalic acid, wh passed into solution as its sodium salt. After boili for 10 minutes, the solution was filtered hot, the sm amount of residue being washed with hot water un the washings were clear. The naphthalic acid w then precipitated from the filtrate by the additi of hydrochloric acid, filtered off, washed, and drie Yield 55 g. (95·5% of theory).

The author wishes to express his thanks to Pr R. Robinson for suggesting this investigation, a to The British Dyestuffs Corporation and the Co mandant, Artillery College, for permission to pub the results.

Artillery College, Woolwich.

JOURNAL *of* THE SOCIETY OF CHEMICAL INDUSTRY

CHEMISTRY & INDUSTRY

Official Organ of the Federal Council of Pure and Applied Chemistry

which consists of Representatives from

The Chemical Society, the Society of Chemical Industry, the Association of British Chemical Manufacturers, the Institute of Chemistry, the Society of Public Analysts, the Faraday Society, the Institute of Brewing, the Society of Dyers and Colourists, the Society of Glass Technology, the Iron and Steel Institute, the Ceramic Society, the Institution of Gas Engineers, the Society of Leather Trade Chemists, the Royal Photographic Society, the Mineralogical Society, the Biochemical Society, the Institute of Metals and the Royal Agricultural Society.

VOL. 43 NEW SERIES | LONDON, DECEMBER 5, 1924 | NO. 49

EDITORIAL

A FEW weeks ago there was a singular and distressing outbreak of cases of poisoning by lead tetraethyl in the United States. This compound was discovered in 1854, but achieved no commercial importance until comparatively recently. Mr. T. Midgley found that it could be mixed with petrol and that the mixture was more efficacious for driving motor-cars and was less liable to knock than ordinary petrol. One part of lead tetraethyl was mixed with about a thousand parts of petrol. The lead tetraethyl was made by the E. I. du Pont de Nemours Company at Wilmington, and also made and mixed with petrol by the Standard Oil Company at Elizabeth, New Jersey. Lead tetraethyl is a particularly poisonous compound and may cause delirium, insanity and death. Five deaths from this form of poisoning recently occurred at the Standard Oil Company's works at Elizabeth, and eight or nine people are alleged to have been killed by it at the du Pont works at Wilmington. The Board of Health of New York has prohibited the use of petrol containing lead tetraethyl and the New Jersey State Department of Health has made a similar order. The Standard Oil Company has discontinued the manufacture and sale of the mixture and a careful investigation of the methods of manufacture and use of lead tetraethyl is now being conducted.

* * *

It was pointed out by Sir Robert Hadfield, Mr. C. A. Klein and others, at the meeting of the London Section last Monday, that there are many methods of protecting surfaces from corrosion or weathering. If a body is to be subjected to so much friction that the surface is constantly being worn away, it is obviously useless to coat this with a covering of no greater power of resistance than the original body. A knife blade, if in constant use, is always losing its surface; it is useless to electroplate it, the only cure is to alloy the steel with sufficient chromium to keep it rustless. A knife that is to be used at rare intervals might with advantage be plated with nickel or chromium to prevent its corrosion in the long intervals between its use. The protection of wood varies with its use and other circumstances. Sometimes you must impregnate it with oil or creosote, sometimes you must paint it; your paint will not necessarily be the same for wood in your drawing room as for your greenhouse roof. Varnishes, polishes, cellulose dopes, oils and waxes all have their own special powers of resistance; we think the distinction drawn between protection of a body from wear and protection of a body from weather is sound. A boy who climbs every wall in the vicinity requires protection for his clothes differing from the protection his mother provides for her fur cloak when she puts it away because the cold and wet weather has set in. The protection of stone is singularly difficult in the air of a great city. Stone is so compact that it cannot easily be impregnated, but it is so porous that water and various solutions can penetrate in places so deep that great damage is done when the water freezes or the solution crystallises. Some day the chemist will show us how to convert an inferior sandstone into a superior granite: it may not be so easy to convert chalk or limestone into a really durable material.

* * *

The joint meeting of the Oil and Colour Chemists' Association with the London Section of the Society of Chemical Industry, which was held at Burlington House last Monday provided many subjects for reflection. The meeting was fortunate in having Sir Robert Hadfield to open the discussion, on "Protective Paint Coatings," and although, as Sir Robert said, his contribution, dealing with the production of alloys resistant to corrosion, was not directly concerned with protective coatings, yet it did show how far the metallurgical chemist, approaching the subject from a different standpoint, had proceeded in the endeavour to do without paint altogether. How difficult the chemistry of paint is was amply shown by the various speakers, a serious difficulty being the necessity for practical exposure

tests, involving considerable expense and a long delay. As the chairman, Dr. Bernard Dyer, said, there must be very few chemists who, at some period in their career, do not have to face some problem connected with paint, and Dr. Fox showed how harassed the chemist can be when such problems are presented. It was of singular value to consider the subject from the industrial as well as the user's standpoint, and the discussion must have impressed everyone in the large audience with the need for more chemists and more chemistry in the paint and varnish industry. Had we more chemists of the type of Dr. Morrell to devise ingenious apparatus and methods such as those which he described for testing the permeability of varnish films; were there more chemists like Dr. Fox to talk to us confidentially and show the limitations of chemical analysis, with a Mr. Klein or two to hold the balance on the practical side, progress would be rapid. The meeting on Monday showed some of the gaps in our knowledge and provided a stimulating atmosphere in which to discuss them. Excellent as are the products of the paint and varnish manufacturer—the London bus, with its gay colours, is a convincing witness—who could be so bold as to say that improvement is impossible? Discussion lights up the path along which advance is profitable. That this path may be distinctly thorny was shown by the summing up by Dr. H. Houlston Morgan, the president of the Oil and Colour Chemists' Association. One point was very striking: the presence of a water-soluble constituent in paint was declared by one speaker to be sufficient cause for rejection of the paint, but another speaker disagreed entirely. This seems a fruitful subject for discussion and we shall hope for enlightenment.

* * *

The Society of Chemical Industry, with its far-flung membership, comprising such a variety of interests centred on chemistry, holds a unique position. This wide scope of the Society and the liberal interpretation which must be given to the word chemistry confer unusual qualities on its *Journal*, qualities that carry with them many problems, as the editorial staff knows full well. One of the most striking features, and one which constantly comes to our notice, is the way in which information given in the *Journal* percolates to sources that are not immediately obvious considering the membership. An article which provokes no comment when it is published may lead to a succession of letters weeks or even months afterwards. A five-line note on some current topic results in a request for further information which arrives the day after publication, and letters relating to the same note may still reach us a couple of years after publication. One kind of letter—that containing an article—always brings a gleam of hope to the editorial eye. Perhaps it is that much desired article on that industrial topic about which no one will write. Perhaps the author is not restricted by the possession of confidential information; perhaps——. Too often it is "alas," not "a visage of joy," but we still hope.

ECONOMY IN STEAM RAISING. II

By CHAS. F. WADE, A.M.I.Mech.E., A.M.I.E.E.

BOILER FURNACES. FIREGRATES. AREAS. [illegible] SUPPLY ARRANGEMENTS. DRAUGHT CONTR[illegible] MECHANICAL STOKERS.

The standard firegrate supplied with a Lancash[illegible] boiler is usually 6 ft. in length, and will vary [illegible] width with the size of the boiler and with vary[illegible] practice of different makers. This 6-ft. grate see[illegible] to be a legacy of past times when the principles [illegible] heat transfer were but little understood and boil[illegible] were only supplied for certain rated outputs [illegible] steam per hour, irrespective of the amount of co[illegible] burned to obtain the required duty or special loc[illegible] conditions of the plant.

Before mentioning practical details of boiler fu[illegible]naces, it is as well to understand thoroughly the tw[illegible] principal ways in which heat is transmitted in [illegible] boiler. These are by direct radiation or the tran[illegible]formation of heat-energy into radiant energy, an[illegible] back again to heat energy on absorption by a[illegible] opaque surface; and secondly by direct conductio[illegible] of heat energy by contact of the comparatively coo[illegible] heating surface with the high temperature gases[illegible] The former method of transfer plays the most im[illegible]portant part in any boiler, being responsible for abou[illegible] 75 per cent. of the heat transferred. The explanation[illegible] of this is that radiation is not interrupted by trans[illegible]parent layers of gases in contact with the heating[illegible] surfaces, while, to conduction, such gas films offer [illegible] very considerable resistance. The most effective way of increasing the heat transfer by conduction is to maintain the velocity of the hot gases as high as possible, so that the inert gas film is reduced to its minimum possible thickness.

The principal object to aim at in any boiler furnace is to maintain as high a temperature as possible with a corresponding maximum radiation activity: this is obtained when the firebed is of the greatest thickness compatible with complete combustion. This thickness will vary according to the amount of air supply available, for it cannot be too well or too often emphasised that the atmospheric oxygen is as much the fuel as the coal or other material usually known by that name, so that, above a certain point, the more air there is used the more wasteful is the operation of the plant. The importance of high furnace temperature will be realised on reference to the laws of transference of heat by radiation as evolved by Stefan and Boltzman, wherein it is given that the amount of heat radiating from an incandescent black body varies in proportion to the fourth power of the absolute temperature. Rankine has laid it down that the total heat transference in a boiler, due both to radiation and conduction, varies as the square of the temperature difference, but the exact variation is very difficult to determine. In any case, it is obvious that the furnace temperature has a very marked effect upon the efficiency of the boiler. If the furnace temperature is low the temperature gradient through the boiler will be reduced as compared with high furnace temperature, or, in other words, the exit tem-

perature of the waste gases will not vary directly with that of the furnace.

The grate area of a Lancashire boiler to give the highest efficiency can only be found by actual experiment, by reducing the area step by step and increasing the combustion rate per sq. ft. of heating surface until a point is reached, determined by local conditions, where the steaming capacity of the boiler commences to fall or the fire thickness is too great for complete combustion. Under average conditions a 4-ft. length of grate is usually found to approximate closely to the best combustion conditions.

The next most important point to consider is the design of the firebars. These should be so designed that the maximum air space is available between the bars consistently with mechanical strength. An ample depth is also necessary in order to present a good surface to the incoming air to cool the bars and incidentally to preheat the air slightly. Numerous thin firebars both distribute the combustion air more evenly throughout the firebed, and are less liable to burn away rapidly, than a smaller number of thicker bars.

The firebridge in cylindrical boilers should always be built as low as possible, and must only be considered as a check against coal being thrown too far beyond the grate. A high firebridge acts as a fixed damper in the path of the gases, and leads to incomplete combustion and trouble from smoke emission.

With hand firing special attention is called for in the regulation of the air supply, both through the firebed and over the fires. The main air control from the individual boiler dampers must always be easily workable and worked from the firing position, while the secondary air supply over the fires should be regulated by means of proper air shutters on the fire doors, and the ashpits should be provided with a damper so as to divert the air from the ashpit to the combustion space until the large volume of volatile matter at first driven off at firing has been largely consumed. Air introduction at the firebridges is not an effective method of consuming the volatile hydrocarbons, but more often arrests combustion and merely dilutes the gases with comparatively cold air. There are many patented devices on the market embodying various forms of hollow firebridges for secondary air supply, but in practice none of these are very satisfactory. By closing the ashpit damper and allowing a larger volume of air to pass over the fires through the firedoor grids, the generation of unmanageably large volumes of gases is retarded by the reduced temperature in the bottom of the firebed, and a larger supply of air is available to mix with the gases above the fires. It may be mentioned here that air in passing beneath the firegrate to a hollow firebridge or other form of secondary air supply at the back end of the grate does not become appreciably preheated, as is sometimes claimed, as the air is only exposed to radiation and not conduction, and is therefore not heated up, owing to its transparency. What little heating may take place is that from the lower surface of the ashpit, and in cooling the water at this point will do more harm than good in reducing the water temperature and reducing circulation, just where it is most required.

Considerable attention is now being given to the use of various low grade fuels such as fine slack coal and coke dust, and, so long as a specially designed furnace is employed, these materials will give perfectly satisfactory results. As a rule the percentage of ash in the class of fuels mentioned is rather high while the calorific value is low. The requirement for a furnace to burn low grade slacks is that it shall have a sufficiently powerful draught to maintain a high rate of combustion and at the same time the formation of large masses of clinker must be reduced as far as possible. Fine slack coals and coke dust pack closely together on the firegrate so that a high draught pressure is necessary in order to overcome the resistance to the passage of air through the firebed and at the same time to maintain a sufficiently rapid combustion rate to obtain a reasonable duty from the boiler. There are several excellent makes of forced draught furnaces available which will burn high ash fuel efficiently with but little combustible matter removed with the ashes. All these furnaces employ an arrangement of steam jets to maintain sufficient pressure in the ashpit, and the effect of the steam on the firebars prevents the formation of masses of clinker, which remains in a granular form and can be raked out rapidly when cleaning fires.

When burning coke or other low volatile fuel forced draught is always necessary in order to keep the whole of the mass of fuel at incandescence, if anything approaching high efficiency is to be obtained. The reason for this is that with low rates of combustion the secondary, reducing action of the carbon in the upper layers of fuel on the grate reduces the surface temperature by its endothermic effect and the carbon monoxide resulting burns with a flame which is deficient in radiant energy, so that heat transference is mainly dependent upon conduction instead of radiation.

When speaking of the "furnace" of a boiler the combustion engineer includes in that description the whole of the boiler furnace proper and the flues around the boiler. The requirements as to high velocity of gases in order to effect the maximum conduction transmission are, in cylindrical boilers, greatly restricted owing to the necessity for sufficient space for access purposes. The utility of such devices as firebrick obstructions in the flue tubes is limited by the amount of draught power available, for although the velocity of the gases may be accelerated by the insertion of, say, a firebrick cylinder, yet the air supply to the fires may be so reduced thereby as to result in a diminution of combustion rate that will more than offset the advantage obtained by the increased velocity of the gases.

In water-tube boilers attempts to increase the velocity of the gases by the addition of baffling so that the path of the gases is lengthened and narrowed have mostly resulted in increased final temperatures for the gases instead of the expected reduction, although the furnace temperature has been lowered. This result is explained in the same way as that given above. Another result of adding

baffling to vertical water-tube boilers which also reduces efficiency is that caused by the actual covering up of appreciable portions of the tube surfaces by the extra baffles, this taking place usually where, in the absence of the extra baffles, the hot gases would directly impinge. By altering the actual system of tubing so as to maintain or increase the velocity of the gases as their volume decreases with the temperature, the difficulties referred to above are overcome, as in the present writer's recently patented system of tubing. In this arrangement each successive bank of tubes is of the same aggregate heating surface, but composed of smaller tubes grouped more closely together so that the area of the gas passage occupied decreases proportionately to reduction of the gas volume, thus maintaining the velocity.

The water-tube boiler has a great advantage over the internally-fired boiler in that there is but little limitation of combustion space and a very large combustion chamber may be provided for thorough combustion of large quantities of fuel before partially burned gaseous products reach the comparatively cool heating surfaces. In older water-tube boilers, set low over the fires, high combustion and evaporation rates were prevented because the hydrocarbons reached the tube surfaces before combustion was complete and were thus arrested, with the formation of more or less black smoke. In more recent installations the boiler is set some feet above the firegrate surface so that combustion is perfect before contact is made with the heating surfaces, while the direct exposure of the latter to radiation from the firebed is not interrupted.

In order to provide more combustion space in Lancashire and similar boilers experiments have been made with various forms of external furnace, but none of these has met with any large measure of success owing to the fire surface being screened from the heating surface and practically the whole heat transmission having to be effected by conduction. The provision of an inverted arch for a few feet within the mouth of the flue tube would be very effective in providing an incandescent radiating surface to project the heat on to the heating surface.

Mechanically fired furnaces have their widest field of application in conjunction with water-tube boilers, while there are only a few types which are satisfactory with internally-fired boilers. The principal drawback in the latter case is the difficulty of seeing how the fuel is distributed over the firegrates so that the necessary adjustments can be properly carried out. The construction of water-tube boilers, on the other hand, lends itself to the provision of ample sight holes in the sides of the furnace so that the state of every portion of the fires can be observed readily. The limited space available in a furnace tube also prevents the adoption of anything approaching a travelling grate arrangement, so that the feeding of the coal down the grate of a Lancashire boiler is never so definite as with the travelling grate stoker of a water-tube boiler.

The sprinkling type of stoker greatly outnumbers all others for firing Lancashire boilers and this class of machine will deal very satisfactorily with low-grade fuels of most descriptions. The air is usually supplied under pressure from steam jets and the firebar arrangements approximate very closely to those employed for the hand-fired furnaces already mentioned.

In the absence of steam storage, mechanical firing is at a disadvantage compared with hand method when the demand to be met is subject to heavy and rapid fluctuations as is very widely the case in the chemical industries. Where the forced draught is supplied by means of steam jets and there is an appreciable fall of steam pressure due to a sudden heavy demand for steam, it is a frequent occurrence that the reduced steam pressure prevents anything approaching a heavy fire being worked up owing to the decreased effect of the jets. This means that a good reserve of boiler capacity must always be available in order to avoid trouble from fall of steam pressure.

The efficient operation of mechanical stokers calls for quite as much intelligence as hand firing although the need for physical effort is greatly reduced in the former case, and it is a fact that, until some device for automatic regulation of the fire speed and thickness by the composition of the waste gases is evolved, coupled with damper regulation in the same way, the necessity for scientific and intelligent human control will not be reduced.

Some mention may be made of methods of automatic draught control. These all derive their initial means of operation from the variations of steam pressure, and if control of the stoker feed is not combined with the damper control there are circumstances under which such devices will be quite the reverse of economical. A fall of steam pressure may be caused through holes in the fire or thin patches, so that on the damper opening under this influence more cold air than before will be drawn through the boiler, resulting in further lowering of steam pressure and more uneconomical furnace conditions. Closing of the damper under the influence of a rise of steam pressure will probably result in a deficiency of air for the fuel on the grate so that incomplete combustion results with the presence of carbon monoxide and probably black smoke.

The best method of hand control of fires is by means of the differential draught gauge in conjunction with a steam flow meter, either combined in one instrument, as in the Bailey boiler meter, or by the use of two separate instruments.

A simple calculation will show that the amount of oxygen or air required to produce a given number of heat units is very nearly constant over a range of solid fuels ranging from semi-anthracite to low-grade semi-lignites. Also in a given boiler, when all other things are equal, the rate of steam generation is a measure of the amount of heat being generated, and the fall of draught pressure from the boiler side of damper to the combustion space over the fires provides a measure of the relative air-flow. Thus, with the boiler working at its best efficiency there will be an approximately constant relation between the reading of a differential draught gauge, connected at the points mentioned, and that of a steam flow meter, connected in the boiler steam branch. Initial calibration of such a

combination is made by careful adjustment of the air and fuel supply, with the assistance of an Orsat apparatus, so that the best combustion conditions are obtained and then marking the dial of the differential draught gauge with the corresponding steam meter reading. This operation is repeated for different values of steam flow and the fireman will then have a direct guide to the correct damper or fan adjustment for the particular rate of steaming obtaining at any time.

In the Bailey boiler meter, a single circular recording chart is employed. Two mechanisms record on the same chart, one being a steam flow recorder and the other a differential draught recorder. The instrument is so adjusted that when the correct relation between the two factors exists the line traced by each pen is superimposed. If there is too much air for the amount of fuel on the grate or the steam flow rate, the draught line will be above the steam line. If at any time it is found impossible to make these lines correspond it is a direct indication that there is some defect in the boiler which calls for rectification. Thus, a dirty boiler will render it impossible to get the air line down to the steam line even though the air is in correct proportion to the fuel being used, the apparent discrepancy being caused by the reduction in the amount of steam being generated for the amount of fuel being used.

ON THE HISTORY OF POTABLE GOLD

In the *Chemiker Zeitung* (112, 653 and 678), Dr. Ernst Darmstaedter—who will be remembered for his recent book "Die Alchemie des Geber"—has an interesting article entitled "Zur Geschichte des 'Aurum Potabile.'" Darmstaedter first of all considers the question of how the metals originally came to be used in medicine, and brings forward evidence from the Atharvaveda, Yajurveda and other ancient Sanskrit literature in support of his suggestion that the supposed relationship between the sun and moon and gold and silver respectively may have led men to drink a suspension of gold in water in order to acquire the vitality of the solar god. In the Indian ritual gold was closely connected with Agni, the fire-god. The Susruta medicine describes the preparation of a "gold drink" by beating out gold into thin leaves, heating it strongly six or seven times, and then dissolving it in various liquids. The drink so obtained was used as an aphrodisiac, etc.

In this connexion it may be noted that the ancient Egyptians regarded gold (as well as malachite and other substances) as essentially a *giver of life*, and according to the Elliot Smith and Perry school of archæologists, it was their industrious search for sources of these givers of life which led the Egyptians to construct sea-going ships and thus to spread the archaic civilisation all over the world.

Darmstaedter next considers the use of honey in medicine. Honey is often mentioned in Vedic literature, and its golden yellow colour may explain why it was frequently used, like gold, in the preparation of elixirs of life.

Greek medicine apparently made no use of gold and silver for healing purposes. Such application is, however, found in the Pharmacology of the Persian Abu Mansur Muwaffak, in the tenth century. Abu Mansur Muwaffak has, incidentally, another claim to distinction: he was the first to mention the use of plaster of Paris in surgery.

Similarly Ibn Sina (Avicenna, died 1036), in his Qānūn or Canon of Medicine, recommends the addition of gold to medicines used in case of melancholia, and says that, as a collyrium, it strengthens the eyes.

In medieval European medical practice potable gold found extensive application. It is mentioned by Arnaldus de Villanova, Vincent de Beauvais, Albertus Magnus, Thomas de Cantimpré, Konrad von Megenberg, and other well-known writers. It seems to have been a solution of gold chloride or occasionally colloidal solutions of gold. Ulstadius, Gesner and Paracelsus all extol the virtues of *aurum potabile*, and although at first the idea was quite independent of alchemy, the two soon became, and remained, closely connected.

Darmstaedter appears to attribute the discovery of fulminating gold to "Basil Valentine" (or Johann Thölde), in the "Letzten Testament," Strasburg, 1651. It was, however, well known to Jean Béguin half a century earlier, and is fully described by Christopher Glaser, who was the teacher of Lemery and acquired an unenviable reputation by getting himself mixed up with the notorious *Affaire Brinvilliers*.

Darmstaedter also mentions the well-known bactericidal powers of colloidal gold and suggests that the ancient praises of potable gold have something at least to be said for them. He sums up his conclusions by saying that we can get some idea of why gold was used as a healing and strengthening agent by a consideration of the following facts:—

(1) Magical, mystical and religious ideas.
(2) Alchemical theories.
(3) Practical observations of the action of metals and metallic preparations.
(4) The customs of folk-medicine.
(5) For later times, scientific, pharmacological and medical observations.

SODIUM CARBONATE IN CANADA

In the vicinity of Meadow Lake, 50 miles north of Clinton, British Columbia, the Lillooet Soda Company is operating at a hydrous sodium carbonate lake and shipping the product to Vancouver, over the Pacific Great Eastern railway. This material is being disposed of at the present time to soap manufacturers on the Pacific coast, but plans are under way for the erection of a drying plant to handle the material at the lake and to further increase the output. This Company also owns several other lakes of the same material which they propose to operate at some future date.

FORTHCOMING EVENTS

Dec. 8. BIOCHEMICAL SOCIETY, Imperial College of Science and Technology, South Kensington, at 5 p.m. (1) "The Magnesium of Human Serum," by E. Watchorn. (2) "The Oxidation of Amino Acids by Fungus Tyrosinase," by M. E. Robinson and R. A. McCance. (3) "The Isolation of a Hydrolysis Product of the Proteins hitherto Undescribed," by H. W. Buston, H. N. Mukherjee and S. B. Schryver. (4) "Some Transformations of Casein," by H. Martin and S. B. Schryver. (5) "The Separation of the Proteins of Egg-White in an Electrical Field," by D. Griffiths and S. B. Schryver.

Dec. 8. INSTITUTE OF BREWING, *London Section*, Engineers' Club, 39, Coventry Street, London, W. "Removal of Nitrogen from Wort by Yeast during Brewery Fermentation," by H. F. E. Hulton and J. L. Baker.

Dec. 8. CERAMIC SOCIETY, Central School of Science and Technology, Stoke-on-Trent, at 7.30 p.m. "Notes on Crushing and Grinding Mills," by F. Lane.

Dec. 8. ROYAL SCOTTISH SOCIETY OF ARTS, 117, George Street, Edinburgh, at 8 p.m. "Stone Decay and Preservation of Buildings," by Principal A. P. Laurie.

Dec. 8. ROYAL SOCIETY OF ARTS, John Street, Adelphi, London, W.C. 2, at 8 p.m., *Cantor Lecture*. "Modern Colour Problems," by Dr. L. C. Martin (Lecture 3).

Dec. 9. SOCIETY OF CHEMICAL INDUSTRY, *Birmingham and Midland Section*, the University Buildings, Edmund Street, Birmingham, at 7.15 p.m. "The Role of Silica in Plant Growth: its Assimilation, and Physiological Relation to Phosphoric Acid," by D. R. Nanji and W. S. Shaw.

Dec. 9. FARADAY SOCIETY, Rooms of Chemical Society, Burlington House, Piccadilly, London, W. 1, at 4.30–7.30 p.m. "Base Exchange in Soils," by Dr. D. J. Hissink; "Role of the Electronegative Ions in the Reaction between Soils and Electrolytes," by N. M. Comber; "Studies on Base Exchange in Rothamsted Soils," by H. J. Page and W. Williams; "Base Exchange in Relation to Soil Activity," by G. W. Robinson and R. Williams; "Relation between the p_H Value, the Lime Requirement and the Thiocyanate Colour of Soils," by S. J. Saint; "Some Secondary Aspects of Base Exchange in Soils," by E. A. Fisher.

Dec. 9. SOCIETY OF CHEMICAL INDUSTRY, *Glasgow Section*, The Ramsay Chemical Dinner, at the Ca'doro Restaurant, Glasgow.

Dec. 9. SOCIETY OF DYERS AND COLOURISTS, *Leeds Junior Branch*. "The Tinctorial and Antiseptic Properties of Certain Types of Quinoline Dyestuffs," by P. G. Marshall.

Dec. 9. ROYAL PHOTOGRAPHIC SOCIETY, *Scientific and Technical Group*, 35, Russell Square, London, W.C. 1, at 6 p.m. Discussions will take place on (1) "The Light Source, Primary and Secondary," opened by J. W. T. Walsh. (2) "The Exposure Mechanism," opened by S. O. Rawling. (3) "Development," opened by W. Clark.

Dec. 10. INSTITUTION OF CHEMICAL ENGINEERS. The meeting arranged for this date has been cancelled.

Dec. 10. UNIVERSITY OF LONDON, University College, Gower Street, W.C. 1, at 5.30 p.m. "Technical and Scientific Libraries," by A. Gomme.

Dec. 10. INSTITUTE OF CHEMISTRY OF GREAT BRITAIN AND IRELAND, *Manchester Section*, The Engineers' Club, Albert Square, Manchester, Concert at 7 p.m.

Dec. 11. INSTITUTE OF CHEMISTRY and the SOCIETY OF CHEMICAL INDUSTRY, Joint Meeting, the Pharmaceutical Hall, 36, York Place, Edinburgh, at 7.30 p.m. "Fumigation with Hydrogen Cyanide," by Lieut. Col. W. Glen Liston.

Dec. 11. INSTITUTE OF METALS, *London Section*, 85-88, The Minories, Tower Hill, E. 1, at 7.30 p.m. "Present Problems and Developments in Engineering Bronze Foundry Practice," by F. W. Rowe.

Dec. 12. IMPERIAL COLLEGE CHEMICAL SOCIETY, Royal College of Science, South Kensington, S.W. 7, at 5 p.m. "Some Knots in the Organic Chemical Tangle," by Prof. A. Lapworth.

Dec. 12. INSTITUTE OF BREWING, *Midland Counties Section*, Annual Meeting and Dinner at the Queen's Hotel, Birmingham.

Dec. 12. INSTITUTE OF METALS, *Swansea Section*, University College, Singleton Park, Swansea, at 7.15 p.m. Discussion on "The Design of Furnaces for Annealing and Heat Treatment."

Dec. 12. SOCIETY OF DYERS AND COLOURISTS, *Manchester Section*, "Recent Experiments on the Behaviour of Aluminium Hydroxide towards Dyestuffs and Salts," by J. K. Wood and A. Wooller. "On Alkali Cellulose," by Prof. E. Knecht and J. H. Platt.

Dec. 13. SOCIETY OF CHEMICAL INDUSTRY and INSTITUTE OF CHEMISTRY, *Birmingham and Midland Sections*, The Annual Dinner, Queen's Hotel, Birmingham at 6.45 for 7 p.m.

Dec. 15 to 20. UNIVERSITY OF LEEDS. Jubilee of the Yorkshire College of Science, and Coming of Age of the University.

Dec. 16. WEST OF SCOTLAND IRON AND STEEL INSTITUTE. "The Application of Producer and Coke Oven Gas to the Metallurgical Industry," by Prof. R. V. Wheeler.

Dec. 17. INSTITUTE OF CHEMISTRY, *London Section*, 30, Russell Square, London, W.C. 1.

Dec. 18. INSTITUTE OF CHEMISTRY, *Belfast and District Section*, Queen's University, Belfast, at 7.30 p.m. "The Rutherford-Bohr Atom from a Chemical and Physical Standpoint," by Dr. R. C. Johnson.

Dec. 18. SOCIETY OF DYERS AND COLOURISTS, *West Riding Section*, "The Blending of Materials in the Woollen Trade with Relation to Dyeing," by J. W. Radcliffe.

Dec. 19. SOCIETY OF DYERS AND COLOURISTS, *Scottish Section*, "Celatine Colours and their Application," by J. W. Wilson.

Dec. 19. SOCIETY OF DYERS AND COLOURISTS, *Midlands Section*, "Destruction of Wool by the Action of the Atmosphere," by S. R. Trotman and R. W. Sutton.

Alteration.—The January meeting of the Manchester Section of the Society of Chemical Industry which had been arranged for January 2 is now arranged for January 9. In this meeting it is hoped that in addition to the paper by Messrs. Simpkin and Sinnatt, the Section will have the honour of welcoming and hearing a paper by Prof. Hugh S. Taylor of Princeton University, U.S.A., the title of his address to be "The Properties of a Catalytic Surface."

SOCIETY OF CHEMICAL INDUSTRY

SUSPENSION OF ENTRANCE FEE

As an inducement to Chemists to become members, the Council has resolved that no entrance fee shall be paid by members joining the Society in 1925.

A form of application for membership was inserted at the end of this Section in the issue of the Journal for October 17, and it is hoped that it may be used to introduce a new member for next year.

BACK NUMBERS OF JOURNAL

The General Secretary will be glad to hear from Members or Subscribers who have copies of the *Journal* for January 4, June 13 and 27, July 4 and 25, September 19, or October 3 and 17, 1924, that they are willing to dispose of to the Society.

BIRMINGHAM SECTION

At the meeting held on November 11 (*cf. Chemistry and Industry*, Nov. 21, 1924) the following paper was also read:—

Dr. Wardlaw, in presenting a paper on researches on molybdenum salts which were being carried out at the University of Birmingham in conjunction with Messrs. F. H. Nicholls and R. L. Wormell, pointed out that only one molybdenum salt now found extensive use, namely, ammonium molybdate, in which molybdenum had a valency of six. Nevertheless many well-defined salts existed with valencies of five, four, three and two. The present research work dealt with tervalent salts which were of interest from the point of view of chemical theory in that molybdenum from its position in the periodic system should show interesting analogies in its tervalent derivatives with the well known chromium salts. Furthermore, such substances should have powerful reducing properties and uses as mordants.

By electrolytic reduction of molybdenum trioxide dissolved in hydrochloric and sulphuric acids solutions had been obtained from which tervalent sulphates and chlorides had been isolated. The new substances had powerful reducing properties, and in the case of the chlorine derivative comparative stability. From the theoretical standpoint there were also interesting possibilities in this field of inorganic isomerism.

EDINBURGH AND EAST OF SCOTLAND SECTION

The second ordinary meeting was held jointly with the local section of the Institute of Chemistry at Edinburgh on November 19, Dr. Alexander Lauder presiding.

Prof. G. G. Henderson, F.R.S., president of the Institute of Chemistry, delivered an address on "The Profession of Chemistry." He recalled the time when the man in the street only thought of a chemist in connexion with drugs and medicines. This conception was to a very great extent widened during the war, when the work of the chemist was brought more prominently before the public eye. A second factor in the appreciation of the true work of tho chemist was undoubtedly to be found in Wembley, where very many visitors had examined the exhibits, asked many questions, and come away with a better idea of the world work of the chemist. Over and above these two factors, the Institute of Chemistry for fifty years had been labouring to educate the public and to consolidate the profession. The extent of their success could be measured by the attitude of the Government Departments, who now frequently sought information and assistance from the Institute. However, the end had not yet been attained, and would not be attained until the profession ranked in public appreciation at least equal to any other in importance. It was unnecessary to tell an audience of trained chemists the extent to which chemistry entered into everyday work. What was necessary, however, was to convince their fellow-citizens of the vital importance of their profession to the health and prosperity of the country. To do this efficiently closer co-operation must be brought about between the various chemical societies, so that it would be possible for the whole profession to speak with one voice.

GLASGOW SECTION

A meeting was held on November 26, in the Institute of Engineers and Shipbuilders, Glasgow, when an address on "The Future Prospects of a Clean Atmosphere" was given by ex-Bailie W. Brownhill Smith, the chair being taken by Mr. Douglas A. MacCallum.

Bailie Smith said that a pure atmosphere had a very beneficial effect upon the public health and upon national economy. In Britain, the air of the large cities was very impure when compared with that of American and Continental towns. The returns for 1923, for example, showed that, at Blythswood Square, Glasgow, 370 tons of solid impurities had fallen per square mile. The domestic open grate, burning raw coal, was the chief agent by which the air was polluted. An examination made in Glasgow had shown that the smoke produced per second by burning coal in an open grate contained sixteen million particles of soot. This explained why the greatest quantity of soot fell on Blythswood Square, as it was surrounded with great blocks of office premises, in each room of which there was an open fireplace.

The particles of soot, coated with a layer of oily hydrocarbons, formed the nuclei for the condensation of moisture and absorbed much of the acid produced during the combustion of the raw coal. The presence of these impurities in the air produced dense fogs during frosty and calm weather. During the winter of 1909, when fog was very prevalent in Glasgow, the death-rate rose rapidly, and a high percentage of the deaths were due to diseases of the respiratory system. In the same period, in seven other large towns in Scotland, where no fog occurred, there was little change in the normal death-rate. Another result of the impure atmosphere was the serious damage to buildings caused by acid corrosion. The periodical repair of this damage was a heavy charge on the public funds.

Many suggestions had been made for rendering the air purer, and more extensive use of gas and electricity for heating and cooking would materially help;

but the preference for the open grate militated against the widespread adoption of such remedial measures. The great hope seemed to be the low-temperature carbonisation of coal by which a smokeless fuel and power gas were produced, together with the recovery of the valuable by-products.

The Gas Committee of the Glasgow Corporation, in 1909, on the motion of ex-Bailie Smith, appointed a sub-committee "to inquire into and report on any process of gas making which will produce a form of coal residue that may be available for use in ordinary grates." The sub-committee reported that the process invented by Mr. Robert Maclaurin—a member of the Glasgow Section—had been tested at Port Dundas electricity generating station, and had been found very satisfactory. The investigations, temporarily interrupted by the war, had been completed and many different coals had been tested.

The results were very satisfactory, and in September, 1923, sanction was given for the erection of a five-unit battery of Maclaurin producers at Dalmarnock to produce smokeless fuel and supply the Dalmarnock electricity station with power gas. This installation was described in detail and the main advantages mentioned: (1) the low capital expenditure involved, and (2) the great elasticity of the process whereby smokeless fuel or coke, with increased production of gas, can be obtained as desired. Incidentally it had been proved that it was possible and cheaper to fire the boilers of the power station with the gas from the Maclaurin producers than by the present system of coal firing.

It was hoped that the Maclaurin process would materially hasten the coming of a pure atmosphere, and it was suggested that each new housing scheme could have its own carbonising plant, which would produce the fuel and gas required for local needs.

The interesting discussion which followed the lecture indicated that the subject of atmospheric purity had appealed to everyone present. In conveying the thanks of the Section to the lecturer, the Chairman said that the citizens of Glasgow were fortunate in having such an able exponent of the benefits of pure air as ex-Bailie Smith. Bailie Smith had identified himself with the subject for many years, and had served on the Royal Commission on Smoke Abatement. The members of the Section hoped that the desired end was now in sight, and they also expressed their thanks to their co-member, Mr. R. Maclaurin, for his material help towards the solution of such a vital problem.

LONDON SECTION

A joint meeting of the London Section and the Oil and Colour Chemists' Association was held at Burlington House on December 1, to discuss the subject of "Protective Paint Coatings." Dr. Bernard Dyer, Chairman of the Section presided, and he was supported by Dr. H. Houlston Morgan, President of the Oil and Colour Chemists' Association.

The discussion was opened by Sir Robert Hadfield, F.R.S., who, after summarising the various theories of corrosion, said there was yet no general agreement as to the fundamental principles involved. Apart from external coatings, however, there was the resistance to corrosion which might be offered by a metal itself. A striking advance in this direction was made on the introduction of alloys of iron and chromium. Thus the resistance of these chromium alloys to corrosion in the atmosphere at the east end of Sheffield was about ten times that of very pure ingot iron. In Sheffield tap water, the loss in weight per unit area of the chromium alloy was under one-eightieth that sustained by the ingot iron. More recently, alloys of iron containing nickel and chromium had been provided which offer effectual resistance over a much wider range of conditions, and were not merely unattacked at ordinary temperatures, but are scarcely affected at a red heat, or even higher temperatures.

Dr. R. S. Morrell discussed the water absorption and permeability of varnish films, and described the apparatus he uses for preparing and testing the films. The only chance for British oil and colour chemists to retain varnish and paint as a protection for metals would be to provide coatings which would not crack on exposure and were of very low water absorbing properties, and, moreover, did not allow metallic iron to pass through them, although they might allow water to pass. He believed it would be possible to fulfil all these conditions. The water absorption could be reduced to a very low figure, and yet maintain the elasticity which was so essential for durability. At the same time, there were many varnish coatings that only allowed water to pass through with difficulty, and yet they were no good as protectors because they deteriorated so quickly on exposure, and cracked. It might be concluded that there was a chance of getting a varnish that had a very low water-absorbing power, that would be elastic enough to stand extremes of temperature and, moreover, would refuse to allow metal to pass through with the water.

Mr. J. N. Tervet gave a description of some interesting results obtained by exposure tests on iron and steel.

Mr. C. A. Klein, dealing with the subject from the general and not the academic point of view, said the word "protective" as regard paints and varnishes was only a relative term in that the paint and varnish trade was not able to supply materials that would be protective against all kinds of corrosion under all conditions, and for all time. Therefore, in dealing with any protective coating, it was necessary to bear in mind the length of time the film would give protection, the particular corrosive influence to be dealt with, and finally, there was the economic aspect to be considered. Protection and cost were two expressions in this matter which could not be separated. On any large painting job 75 per cent. of the cost was for labour, and only 25 per cent. for materials, and therefore there was not much good in trying to save 6d. a gallon on the paint or varnish, and getting an inferior article. The reliability of any coating depended also upon the skill with which it was applied, and the conditions under which it was applied. The great need was skilled craftsmanship, as opposed to the too general idea that anybody could apply paint. This, however, was largely the fault of the manufacturers themselves, who sold ready-

made paints and advised people to do their own painting. He agreed with the tendency to emphasise the importance of physical tests of the properties rather than chemical analysis. It was not always the fault of the paint manufacturer that paints went wrong, because we in this country could and did make good paints and varnishes, although there was a good deal of rubbish on the market.

Dr. J. J. Fox said there were several points which needed clearing up in order to get some clear idea of what we were doing when testing. What was required was a method of testing which would determine, in a reasonably short time, whether a paint would be good or not, and such a test we had not got at the moment. There was great difficulty in interpreting results when they had been obtained. At present the pigment could be tested fairly easily but what about the medium? Supposing the original oil contained foots, a fairly objectionable feature, how could this be found out? There were many conditions under which this could not be determined. One of the chief things in the chemical examination of paints to-day was to get at the medium, if possible, and he did not for the moment see how that was to be done, in mixed paints, if they contained linseed oil or tung oil. In order to get round the difficulties of the chemical analysis, it had been said that we must adopt physical tests, and the question then arose what physical tests should be adopted. Many of them had been tried. There was the plasticity test and the emulsification test and the loaded needle test. He was afraid that what he had said had been all on the negative side but he hoped it would induce the makers to say something.

Mr. W. F. Reid said he was interested in paint as a mechanical protector as used in the linoleum trade. From the very earliest days, it had been found that a good linoleum could not be manufactured unless there was a certain percentage of oxide of iron mixed with it. In the same way, oxide of iron paints were largely used. There was, however, another ingredient that was even better than oxide of iron for external work and that was graphite, because that gave the very important property of resistance to wetting. A paint containing graphite did not permit water to adhere to it.

Mr. A. S. Jennings agreed with Mr. Klein that the encouragement of amateur painters was to be deplored. What was required was more service tests, and he believed the Engineering Standards Association was to take this matter up. This work needed to be done on a very large scale and he hoped it would be done by chemists supervising the mixtures and expert craftsmen applying them. It was essential in such practical service tests that they should have the assistance of skilled craftsmen. Moreover, every-day conditions must be followed absolutely. Very often in paint tests, the paint to be tested was put on to bare wood, whereas in practice there was always the priming coat and then the under-coat before the final paint—and the one to be tested—was put on.

Dr. H. Houlston Morgan said the whole subject of protective paint coatings teemed with difficulties, and the whole industry was at sixes and sevens over the matter as a result of the complexity of it. It was necessary to test and investigate paints and varnishes as complete substances and not to take the medium or pigment separately and form a judgment of the properties of a paint from such a single investigation. These separate investigations were necessary and must be carried out, but individually they must not be used to say that a paint was good or bad. He did not agree with Dr. Morrell that if a varnish emulsified by the absorption of water it was not a durable varnish. Paint and varnish films were always changing; the drying and hardening of a varnish film was a continuous process; it was never the same from the day it was put on until the day it disintegrated and peeled off two or three years hence. Therefore, before we could draw any drastic conclusions as to the water absorption through varnish, the emulsifying effect of water on varnish and its durability, very rigid conditions must be laid down as to the state of oxidation, the condition of dryness and so on, before its properties could be determined. More than that, we must find out the relation between those conditions and the proved durability of a similar film, and these were things we know very little about. Sir Robert Hadfield had shown the value of patient research by the results obtained with the production of rust-resisting steels, and he could only hope that the paint and varnish industry would take that lesson to heart.

OTTAWA SECTION

Dr. A. E. Macintyre presided over an attendance of 38 at the meeting held on November 13, 1924. The Secretary read a letter from the General Secretary intimating that the Entrance Fee had been suspended by the Council for members joining the Society in 1925. The benefits derived from membership in the Society were pointed out, and all who are not now members were urged to join the Society. The Secretary was asked to secure information regarding films disclosing chemical operations which might be secured for exhibition before the Section.

Dr. A. E. Macintyre then gave an address on "Some Aspects of the Chemistry of the Home." One or more divisions of all the sciences had application in the home, but those responsible for its management had little actual tuition in the applied sciences. Chemistry had a wide application in the home in the composition, conservation, and evaluation of all materials entering it, in the preparation of foods, the tarnishing and cleaning of metal articles, laundrying, and so on. Quantitative accuracy should be attained in recipes. Evaluation of food in calories was not sufficient, and the so-called food accessories should also be maintained. The dangers of carbon monoxide poisoning were considered, and the reactions by which the gas is formed explained. The processes of colouring non-ferrous metals were described, and the tarnishing of gold and silver articles, as well as the chemistry involved, was clearly explained. The processes of dyeing and the relation of animal and vegetable fibres to the various classes of dyes were discussed. The amount of chlorine in Ottawa water supply and the corrosion caused by it were also referred to.

YORKSHIRE SECTION

At the second meeting held on November 17, Mr. J. Evans in the chair, Mr. G. F. Pickering read a paper on the "Chemistry of the Distillation of Fatty Acids." After dealing with the infantile state of the analytical control and his own failure to obtain an insight into the nature of the mixed glycerides by fractionating the bromides, or by correlating pitch yield and iodine value, the author stated that the relationship free fatty acids—$\frac{3}{4}$ oxyacids present/total fatty acids = 1 had been found to hold good. It had taken a lot of getting, but only a fourth of the oxyacid distilled off. For candle making the pressing was best carried out after the acids were redistilled. The manufacture was then dealt with, and it was shown that during distillation, oxyacids were formed and carbon dioxide was always evolved. In the distillation of wool grease an unsaturated hydrocarbon, iodine value 60—70, which yielded a fatty acid on treatment with the Grignard reagent, had been definitely found; there was also (to the extent of 2—3 per cent.) anhydride formation and polymerisation of unsaturated acids. The paper concluded with a discussion of the physics of the colloids which required further research to facilitate the pressing of the distillates.

Dr. L. L. Lloyd and the chairman took part in the ensuing discussion.

SOCIETY OF DYERS AND COLOURISTS

A meeting of the Manchester Section of the Society o. Dyers and Colourists was held on November 21 in the Rooms of the Manchester Literary and Philosophical Society. Mr. J. Huebner, M.Sc.Tech., F.I.C., presided. Upon the motion of the chairman, seconded by Prof. E. Knecht, a vote of thanks was unanimously accorded the retiring chairman, Mr. William Marshall, J.P., for his services during his period of office.

A paper was read by Prof. E. Knecht and E. F. Muller on "Some Further Observations Relating to the Action of Heat on Cotton Fabrics," in which it was shown that when bleached cotton was heated for prolonged periods (up to 2000 hours) to 90° C., the material was found to behave differently according as it was exposed in open, sealed, or evacuated and sealed, glass tubes. In all cases, the material had deteriorated in strength, the least affected being that in the evacuated tubes; nevertheless the last-named specimens were scorched or browned more than the others. The deterioration was shown to be due partly to the action of heat *per se* and partly to oxidation. Discussing the question of the effect of higher temperatures, the "danger point" of a flat-iron was estimated to be in the vicinity of 250°.

In a subsequent paper on "The Interaction of Glucose and Methylene Blue," by Prof. Knecht and Miss Eva Hibbert, it was shown that the reducing action on the dyestuff in an alkaline medium could be measured quantitatively and that this reaction could be employed as a convenient and rapid means for the estimation of glucose.

FARADAY SOCIETY

Prof. F. G. Donnan, F.R.S., president, presided at the meeting on November 17, when the following papers were read:—

Principal A. P. Laurie read a note on the "Expansion of Water while Freezing." Assuming that the atomic diameters based on Bragg's crystal model for ice are true for liquid water and that liquid water at 0° is a trihydrol, it is shown to follow as a geometrical necessity that there will be an expansion from 1 to 1·088 when ice melts. This gives a specific gravity for ice of 0·918 and the experimental value is 0·917, thus confirming the original assumptions.

R. W. E. B. Harman and F. P. Worley discussed "The Hydrolysis of Alkali Cyanides in Aqueous Solution." The degree of hydrolysis has been determined by several methods, but results have not been concordant, owing to disturbing factors in the methods used. In that used by the authors the vapour pressure of hydrogen cyanide over solutions of potassium cyanide was compared with that over solutions of hydrocyanic acid. The results are shown graphically and compared with those obtained previously. The degree of hydrolysis of sodium cyanide at 25° at all concentrations was found to be the same as that of potassium cyanide. The effect of temperature was also studied.

The constancy of the hydrolytic constants at different concentrations at each temperature, the agreement of the values at different temperatures with the van't Hoff Isochore, and finally the agreement between the calculated heat of hydrolysis and the measured heat of neutralisation appear to confirm the accuracy of the values arrived at for degree of hydrolysis at the various concentrations and temperatures employed.

A paper on the "Viscosity of Reversible Emulsions" was read by S. S. Joshi. Viscosities of water-in-oil emulsions prepared from castor oil, olive oil and paraffin oil by means of four monovalent soaps are determined. Viscosity increases with increase of the dispersed phase and is maximum at the reversal point which is followed by a sudden drop in viscosity upon inversion. The concentration and the specific chemical nature of the emulsifying agent have no effect on the viscosity of the emulsion. Hatschek's equation for the viscosity of the emulsoids is not followed; observed viscosities are in approximate agreement with those estimated by Einstein' equation for suspensoids; Arrhenius' equation applic better still. The possibility of an increment in th size of the grains of the water-in-oil emulsions wit increase in the proportion of the aqueous phase is suggested.

D. B. Macleod discussed the "Viscosities of Liquids at their Boiling Points." Boiling points are unsatisfactory temperatures at which to compare the viscosities of liquids. By correcting the boiling points to a condition of equal free space, the viscosities of liquids become proportional to their molecular weights in the liquid state. Such a condition of equal free space corresponds very closely to a reduced temperature on the basis of van der Waal's equation of state.

A second paper by D. B. Macleod was on "The Kinetic Theory of Evaporation." It is assumed that the ratio of the density of the vapour above a liquid to the density of the liquid is really the ratio of the number of molecules with sufficient speed to escape from the liquid to the number with insufficient speed. Thus if D_v and D_e are the densities of the vapour and liquid respectively, then, $\frac{D_v}{D_e}=\frac{N_s}{N_i}$ where N_s is the number of molecules with sufficient speed to escape and N the number with insufficient speed. It is shown that the results which follow from this assumption are so simple and satisfactory as to make the truth of the assumption extremely probable.

J. T. Howarth and F. P. Burt described a "New Design for Apparatus to measure the Coefficient of Deviation from Boyle's Law and the Determination of this Coefficient for Acetylene." A modified apparatus for measuring the compressibility of gases has been designed in which the whole volume of the gas and also the mercury column which registers the pressure are kept at the temperature of melting ice. The coefficient of deviation from Boyle's law at 0° C. has been determined for acetylene and its value between 0 and 1 atmosphere found to be —0·00884.

HULL CHEMICAL AND ENGINEERING SOCIETY

On November 25, Mr. A. V. Slater delivered a lecture on "Adsorption" to a large and appreciative audience. The *New York Times* recently called the attention of the general public to the importance of adsorption and Mr. Slater emphasised its universality by saying that most natural and industrial processes occurred at surfaces where one of the substances might concentrate. Adsorption was the process taking place at a surface which resulted in a different concentration at the boundary between two heterogeneous phases. It increased with the rate at which the molecules struck the surface, that is, with increasing pressure or concentration. The amount adsorbed was greater the lower the rate of evaporation of the condensed molecules and this would be low if the adsorbed substance decreased the energy seated at the surface, whether it were surface tension, electric potential difference, or chemical valency forces. A comprehensive theory must reckon with all these forces and Langmuir's came nearest to satisfying this condition. A useful rule which helped in understanding *solution* and which was equally applicable to adsorption, was that the greatest attraction occurred between substances of similar polarity. In some cases adsorption took place because the unlikeness of components caused a liquid to "squeeze out" a solute and the adsorbent then played a neutral part in offering an extensive surface on which the substance might concentrate. Chemical attraction also played a large part in adsorption. Ordinary chemical reactions were due to strong deviations of the orbits of the outer electrons; with complex orbital systems strong deviations resulted in chemical reaction whereas slight deviations resulted in less defined reactions such as adsorption. A thorough study of the orbital displacement of electrons when charcoal adsorbed argon might lead to better understanding of chemical action.

Adsorbent carbon was characterised by a loose amorphous structure having a large proportion of free valencies. It was necessary to form the carbon at low temperatures to avoid graphitisation. Activation consisted in selective oxidation of the hydrocarbons adsorbed during carbonisation. Active carbon adsorbed organic substances in preference to water vapour and inorganic substances: the reverse held true for silica gel.

In emulsification, soaps were adsorbed at the interface and the stability and type of emulsion depended on the relative volumes of the two ends of the soap molecule which was orientated with one part in the oil and the other in the water. Increased lubricating power due to admixture of 1—2 per cent. fatty acid with a mineral oil depended on the adsorption of the fatty acid by the bearing surface, the carboxyl group being held by the metal and the hydrocarbon chain by the mineral oil. A new surface was thus formed by the adsorbed fatty acid which offered less resistance to shear. Catalysis depended upon adsorption which permitted greater concentration of reacting substances at the surface, or "activated" the adsorbed molecules.

A lengthy discussion followed. A point of special interest was the settling of paint pigments. Mr. Slater said that the principles involved were those of flocculation and deflocculation. A deflocculated pigment would settle while a flocculated one remained free. Flocculation was brought about by adsorption of a substance like sodium silicate. Although the principles involved were known it was often difficult in practice to obtain the right conditions because the flocculator might produce other deleterious reactions.

Dr. Thevenez congratulated the lecturer on his clear exposition of a difficult subject and Mr. Lowish seconded the vote of thanks.

GLASGOW UNIVERSITY ALCHEMISTS' CLUB

On November 27, an address, entitled "Science and Mr. Wells," was delivered by Dr. T. S. Patterson, the "Gardiner" Professor of Organic Chemistry, before a joint meeting with the Glasgow University Geological Society, Dr. Tyrrell presiding.

Dr. Patterson said that consistency was very necessary if the scientific novel was to be not only acceptable but satisfying. He wondered if such novels could advance our knowledge; it was noteworthy that many of the forecasted conditions of life came to pass much sooner than had been predicted.

Mr. Wells had succeeded in presenting to us novels which, while affording pleasant entertainment, suggested many interesting possibilities.

The progress of science showed, however, that great discoveries had been made, not infrequently, as a result of research undertaken for entirely different purposes.

Scientific advances were made by pursuing the clues which Nature herself had from time to time revealed, and not by searching for new possibilities.

CORRESPONDENCE

OPTICAL ACTIVITY AND POLARITY THEORIES

Sir,—In your edition of September 12 (p. 917) in reply to a letter from Dr. Boyd, Dr. Rule states that his theory of polarity effects in optically active compounds dealt only with general polar effects and not with induced alternate effects. The general polar effect of a substituent has already been indicated in a paper published in the *Proceedings* of the Chemical Society (1914, **30**, 274) in which it was pointed out that the effect of a substituent on rotatory power was partly due to its disturbance of the intramolecular field of force and attention was drawn to the fact that the rotatory power of cinchotoxine was lowered by the introduction of the benzoyl group, lowered further by the more acidic *p*-toluene sulphonyl group and changed in sign by the introduction of the picryl group. Since, however, the value of the rotatory power of a dissolved substance is a complicated function of several variables, the effect of substitution was put on one side while, by an examination of rotatory powers and refractivities, values were obtained of a constant "b" which Livens had suggested should represent the actual electric force of an asymmetric character acting on the electrons of the active atoms.

Livens at the same time pointed out that the medium, purely by its disturbance of polar force (in the electrostatic sense) should considerably affect rotatory power and also pointed out that constants could be obtained independent of the wave length of the light used.

Furthermore, in the *Proceedings* of the Chemical Society (*loc. cit.*), it was stated that the influence of substituents on rotatory power there described might be explicable on the basis of Flürscheim's theory of strength of linkages, but further work was impossible at the time. Experiments, however, are now in progress with a series of substituted benzyl acetic acids and related compounds to test the applicability of Flürscheim's hypothesis to these results and also the applicability of the theory of induced alternate polarity which Dr. Rule now states is not part of his investigation.

Dr. Boyd in your issue of October 10 points out that if OH is more strongly polar than Cl then glycollic acid should be stronger than chloracetic. A somewhat similar anomaly is shown by *m*-nitrobenzyl chloride; the alternate polarity effect of the nitro group should make this compound more reactive than *p*-nitrobenzyl chloride and the general polar effect should also make it more reactive than benzyl chloride. The velocity constant for the rate of combination of aniline and *m*-nitrobenzyl chloride is, however, lower than that of benzyl chloride and Olivier found similar results by hydrolysis. Slator and Twiss found that the velocity constant with sodium thiosulphate was greater than for benzyl chloride but then the order of m and p was wrong. There is still much to be cleared up therefore. —I am, Sir, etc., D. H. Peacock

University College,
Rangoon

November 8, 1924

PERSONAL AND OTHER ITEMS

Dr. E. F. Armstrong, F.R.S., has returned from a long visit to Canada and the United States. During his stay he gave lectures or talks to the members of the Society of Chemical Industry at Toronto, Ottawa, Montreal and New York, and to the graduates and others at the Universities of Yale, Harvard and Princetown, in addition to an address before the American Chemical Society at Washington. There was ample opportunity to appreciate Dr. Armstrong's devotion to the cause of chemistry during his term of office as President of the Society of Chemical Industry, and his activities as a representative of British Chemistry in the United States have given him a further title to the gratitude of British chemists.

The Main Committee of the British Engineering Standards Association have recently authorised the Secretary, Mr. le Maistre, to accept the cordial invitation of the German Standards Committee (the N.D.I.) to be present at their annual meeting on December 13. He is also going to Prague to give an address on Industrial Standardisation before the recently formed Czechoslovakian Standards Committee.

B. D. Saklatwalla, of the Vanadium Company of America, will be presented with the Grasselli Medal at the December meeting of the American Section of the Society of Chemical Industry.

Mr. L. E. Hinkel has been awarded the D.Sc. degree of London University for a thesis entitled "Reactions in the Hydro-aromatic Series resulting in the Formation of Aromatic Compounds."

After a long discussion, the Swedish Academy of Sciences has decided not to award the Nobel Prizes for chemistry and physics for 1924, but to reserve them for another year.

Mr. H. K. G. Bamber, lately managing director of the Associated Portland Cement Manufacturers, and of the British Portland Cement Manufacturers, who was killed in a motor accident on September 20, left £72,475.

The late Mr. H. H. Dains, technical chemist, left £51,496, with net personalty, £50,434.

The death is announced of Mr. David Moseley, head of the firm of David Moseley and Sons, india-rubber manufacturers, Ardwick, Manchester.

We regret to have to record the death of Mr. J. M. Collett, chairman of J. M. Collett, Ltd., chemical manufacturers, Gloucester, and a member of the Society of Chemical Industry since 1887.

Problems Awaiting Solution

In an address delivered to the members of the guild of undergraduates at Birmingham University, the Warden, Sir Charles Hyde, discussed "The Value of Education and Great Problems to be solved." During his address he quoted statements specially obtained from leading authorities in various branches of science dealing with the problems awaiting solution. The committee of the Institute of Sanitary Engineers suggested that one problem was the full utilisation of the manurial qualities of sewage.

Sir H. Fowler, replying for the President of the Institution of Mechanical Engineers, said that a great question was the very low efficiency obtained in converting heat into work, and thought that a great advance must come in the utilisation of a low potential energy in heat, as exemplified by the tides and the loss of heat in condensing water. Dr. W. R. Ormandy, President of the Institution of Automobile Engineers, considered the outstanding problems were the provision of light alloys having aluminium or magnesium as a base; superior quality anti-friction bearing metals to withstand very high pressures; the conversion of coal into liquid fuels; and the discovery of means for improving the compression value of volatile fuels.

Mr. W. B. Woodhouse, the President of the Institution of Electrical Engineers, wrote that the problems to be solved in electrical engineering were innumerable, the most important problem in electricity supply being that of improving the efficiency of conversion of the energy in coal into electricity. At present the best efficiency obtained was only 20 per cent., though, if methods were adopted which followed experiments now in hand, this would be increased to 30 per cent.

One of the big problems in mining, according to Mr. Humphrey M. Morgans, President of the Institute of Mining and Metallurgy, was mining at great depths, say, deeper than 6000 ft. In metallurgy the problems were to develop methods of treating ever-poorer ores and previous workers' waste at a profit. Physics and chemistry came in here very much.

Canadian Chemical Industry

The financial statement for the year ending March 31 of the Standard Chemical Co. Ltd., of Canada, shows a deficit of $4963 as compared with a net profit of $42,626 for the previous year, and a deficit of $762,368 for the year ending March 31, 1922. The total assets are $6,193,418, of which the chief items are properties, $2,213,315; goodwill, $1,870,724; inventories, $962,927. The principal liabilities are common stock, $1,250,000; preferred stock, $3,602,700; debentures, $488,082; bonds, $310,500; and reserves, $402,457. Sales for the past year amounted to $2,089,396·40. The total wood carbonised during the year was 47,906 cords, which is 8440 cords less than in the previous year. The wood carbonisation industry is suffering from overproduction and the future of the older Canadian plants is obscure.

ERRATA

In the article by Prof. J. C. Drummond, D.Sc., on "Some Modern Tendencies of Vitamin Research," which appeared in the September 12 issue of *Chemistry and Industry*, the words, "one hydroxyl group," on the top line of col. ii, p. 910, should read "two hydroxyl groups."

In the issue of November 28, the following corrections should be made:—On p. 1195, the name of the author of the letter printed in col. i should read: "C. T. Kingzett." On p. 1196, col. i, the price of the silver plaque should be "21s.," not "2s."

REVIEWS

Cadmium, Its Metallurgy, Properties and Uses. By Norman F. Budgen, Ph.D., M.Sc. Pp. xv+239. London: Charles Griffin and Co., Ltd., 1924. Price 21s.

As Professor Turner points out in his "Foreword," no more opportune time could have been selected for the issue of a volume dealing with the occurrence, properties, extraction and uses of cadmium. Recent advances in electrolytic zinc production, a process necessitating the prior removal of cadmium and thus facilitating its recovery, have resulted in ensuring more regular supplies and a reduction in the cost of production which should tend towards an extension of the useful applications of the metal and its compounds.

The book is divided into eleven chapters dealing in detail with the ores and sources, intermediate products and their formation, the production of the metal, statistical information, physical and chemical properties and analytical determination, alloys, electro-deposition of cadmium and alloys and summary of its uses. Each chapter concludes with an excellent list of references giving the authority for practically every description and statement of importance appearing in the text. The author has included the results of some interesting researches of his own, but in the main the chief value of the book lies in the fact that it constitutes, as claimed, a comprehensive digest of all available information, collected with judgment from widely-scattered sources. Both author and publisher are to be congratulated on the thoroughness with which the work has been carried out and presented to the public.

The chief source of cadmium is zinc ores, with which it is invariably associated, but rarely in greater amount than 0·25 per cent. Latterly, the condensed fumes from the smelting of ores of lead and copper have yielded an increasingly important amount of cadmium whose presence is due, however, solely to minerals or compounds of zinc being present in such ores. The author estimates the maximum visible output possible from all sources at 1000 tons annually and the present production at 150 t. It is probable that the latter has now increased to 250 t. which is still 25 per cent. of the possible annual production.

The methods by which metallic cadmium is obtained are described under the three headings—direct distillation, solution and electrolytic precipitation, and solution and chemical precipitation. The first and last have been largely superseded by electrolytic precipitation by which method most of the cadmium is produced to-day. It is necessarily in this chapter that the lack of personal touch with the industry described is more apparent than in any other. Nevertheless, the author has taken full advantage of the material available and has given a well-balanced and readable account of both the old and newer processes.

Probably the greater part of the cadmium production is still consumed in the form of sulphide, a yellow pigment of great permanency, but the metallic alloys are of considerable interest. For

example, one of the most recent applications is its addition to copper for electric transmission wires. Copper wire containing 1 per cent. of cadmium has a higher tensile strength, is harder and more resistant to wear than hard-drawn copper wire and, further, the conductivity is not appreciably impaired. The superiority of this alloy has been proved, particularly in connexion with electrical trolley wires.

William G. Wagner

The Kinetic Theory of Gases. By Prof. E. Bloch. Translated by P. A. Smith. Pp. xiv + 178. London: Methuen and Co., Ltd. Price 7s. net.

The translation of Prof. Bloch's stimulating booklet, the French original of which appeared in 1921, affords to English readers not only an account of the classical kinetic theory, but also of those recent developments which have made the kinetic theory one of the most vital branches of modern theoretical physics.

The first four chapters deal with the classical theory in the form associated with the names of Maxwell and Clausius, and a clear outline account is given of the more important considerations which are characteristic of this stage of the development of the theory. In Chapter 5 the methods of statistical mechanics and the theoretical developments which we owe to Boltzmann are briefly considered, and in Chapter 6 the reader is introduced to the theory of quanta and to those modern views on energy exchange which are associated in particular with the theories of Planck and Einstein.

The remaining four chapters are devoted to the consideration of Brownian motion, fluctuations, rarefied gases, the width of spectral lines and molecular constants. Undoubtedly this is the most interesting part of the book, and the various directions in which modern research has served to amplify the fundamental notions underlying the kinetic theory are clearly expounded. All purely mathematical developments are avoided, the object of the author being to present fundamental ideas in logical sequence, and to show that the kinetic theory is built upon foundations which are almost unassailable.

In some few instances, statements are made which in form or substance are at least questionable. For instance, on p. 63, in a discussion of the distribution of a mixture of gases under the influence of gravity, it is said that "each of the gases distributes itself in height under the influence of gravity as if it were alone, *the law of distribution varying more rapidly* the greater the molecular weight of the gas." Again, on p. 80, there is an argument relative to the heat capacities of gases and the equipartition theory which would not meet with general acceptance. Such minor blemishes do not however suffice to depreciate sensibly the intrinsic value of the book, which can be warmly recommended to all students of physical chemistry.

H. M. Dawson

COMPANY NEWS

SANTA CATALINA NITRATE CO., LTD.

During the year manufacture has been practically uninterrupted, resulting in an output of 15,000 tons of nitrate. Of that quantity roughly 9300 t. have been brought into the accounts, realising with gain on iodine and interest, £23,226 gross, or, after deducting London expenses and a proportion of taxes, £21,099, subject to final adjustment of corporation profits tax, which latter, it is hoped, will appear for the last time in the company's accounts. On account of that profit a dividend of $7\frac{1}{2}$ per cent. was paid last June, and subject to approval, a final distribution of 15 per cent. on the year's operation is now to be made. £1200 has been placed to reserve. Since the end of last season until a few weeks ago, the nitrate market was extremely active, and sales for the current year's supply were brought up to 2,200,000 t.

DUNLOP RUBBER CO.

The company has a nominal capital of £20,000,000, divided into 5,000,000 £1 preference and 15,000,000 ordinary "A," "B," and "C" shares, the whole of the preference shares having been issued with the exception of 108,686. According to evidence given in the Chancery Division on November 19, when a reduction of capital by the company was sanctioned, the gross loss amounted to £12,582,000, but this sum had been reduced by the appropriation of certain reserves and certain other items, amounting together to rather over £2,000,000, the net loss therefore amounting to £10,527,542. It was proposed to meet the loss by reducing the share capital. The bulk of the loss appeared in the balance sheet for the year ended August 31, 1921, and arose chiefly through the depreciation of rubber and cotton and partly on foreign exchange. Preference shareholders had agreed to the cancellation of 4s. per share, making them 16s. each. The rest of the loss fell on the ordinary shareholders whose £1 shares would be brought down in value to 6s. 8d.

SCOTTISH OILS, LTD.

An interim dividend has been declared of $3\frac{1}{2}$ per cent. actual, less tax, on the non-cumulative participating preference shares. No interim payment was made last year, but $3\frac{1}{2}$ per cent. was paid, less tax, at the end of the year, the last dividend on ordinary shares being in 1920, of $6\frac{1}{12}$ per cent.

AMELIA NITRATE CO.

The annual report for the year to June 30, 1924, showed a trading profit of £21,268. The gross profit, including interest received, amounted to £24,548 (£46,075 in 1923 and £4827 in 1922), and the net profit, after deducting interest and London expenses, was £20,385. An ordinary dividend—the first for two years—of 15 per cent., less tax, had been proposed by the Directors, the sum to be carried forward amounting to £5000 as against £5750 brought in. At the annual general meeting it was stated that the company had now £53,000 cash in hand instead

of £2500, cash and securities amounting to £73,000, and stocks of nitrate totalling £128,000 against £142,000. Debts were £45,895, against £70,000. The future of the nitrate industry looked quite hopeful, the shipments for the twelve months ended June 30, 1924, amounting to 2,175,000 tons, an increase of 69,500 t. over last year. Sales for the current year, commencing July 1, both shipped and unshipped, already totalled 1,859,931 t. A dividend of 15 per cent. less income-tax, on the ordinary shares was declared.

BRITISH OXYGEN CO.

This company which, in July last, issued £250,000 additional capital, including a bonus issue of 35 per cent., has declared an interim dividend of 3¾ per cent., less tax, on the capital of £750,000, compared with 3¾ per cent. paid, free of tax, on £500,000 last year.

CASSEL CYANIDE CO., LTD.

The accounts for the year to September 30, 1924, show a net profit of £70,283, which together with the balance of £14,513 brought forward from last year, amounts to £84,796. From this has to be deducted £17,625 for interim dividend of 3d. per share paid in June, 1924, leaving a sum of £67,171 of which it is recommended £52,875 should be disposed of in payment of a final dividend of 9d. per share, the balance of £14,296 being carried forward.

DORMAN, LONG AND CO.

The annual report for the year to September 30, 1924, shows a profit of £504,984, and a balance brought forward of £202,667. No dividend has been declared on the ordinary shares.

ANGLO-PERSIAN OIL CO.

It has been authoritatively announced that H.M. Government has no intention of disposing of its shares in this company, as, on a full examination by the departments concerned, it was satisfied that it would not have been in the national interest to part with the shares to a combine, and, also, that naval interests, for which the original investment in an independent oil company was made, would have been seriously prejudiced.

BRITISH COTTON & WOOL DYERS' ASSOCIATION, LTD.

The accounts for the six months to September 30, 1924, show a profit of £79,597, which includes income from investments, etc., after charging administration expenses, £4266 for specific depreciation, £29,929 for repairs and renewals, and providing an estimated amount for income tax, corporation profits tax, etc. From this amount is deducted £713 for audit fee and other professional charges, £12,400 interest on first mortgage debenture stock to September 30, 1924, £100 debenture holders' trustees, and £12,500 transferred to depreciation fund (now standing at £227,500), which makes a profit for the period of £53,884. The sum of £39,690, being the amount brought forward at March 31 last (after deducting £5250 voted at shareholders' meeting) should be added, leaving a credit balance on profit and loss account of £93,583.

MARKET REPORT

This Market Report is compiled from special information received from the Manufacturers concerned.

Unless otherwise stated the prices quoted below cover fair quantities net and naked at sellers' works.

GENERAL HEAVY CHEMICALS

Acetic Acid, 40% tech. ..	£23 10s. per ton.
Acid, Boric, Commercial—	
Cryst.	.. £45 per ton.
Powder.. ..	.. £47 per ton.
Acid Hydrochloric	.. 3s. 9d.—6s. per carboy d/d., according to purity, strength and locality.
Acid Nitric 80° Tw.	.. £21 10s.—£27 per ton makers' works, according to district and quality.
Acid Sulphuric ..	.. Average National prices f.o.r. makers' works, with slight variations up and down owing to local considerations: 140° Tw., Crude Acid, 65s. per ton. 168° Tw., Arsenical, £5 10s. per ton. 168° Tw., Non-arsenical, £6 15s. per ton.
Ammonia Alkali..	.. £6 15s. per ton, f.o.r. Special terms for contracts.
Bleaching Powder	.. Spot £11 d/d.; Contract £10 d/d. 4 ton lots.
Bisulphite of Lime	.. £7 10s. per ton, packages extra.
Borax, Commercial—	
Crystal	.. £25 per ton.
Powder.. ..	.. £26 per ton. (Packed in 2-cwt. bags, carriage paid any station in Great Britain.)
Calcium Chloride	.. £5 17s. 6d. per ton d/d.
Copper Sulphate ..	.. £25 per ton.
Methylated Spirit 64 o.p.—	
Industrial ..	.. 2s. 7d.—2s. 11d. per gallon, according to quantity.
Mineralised ..	.. 3s. 8d.—4s. per gallon, according to quantity.
Nickel Sulphate .. .. Nickel Ammon. Sulphate	£38 per ton d/d. Normal business.
Potash Caustic ..	.. £30—£33 per ton.
Potass. Bichromate	.. 5¾d. per lb.
Potass. Chlorate..	.. 3d.—4d. per lb.
Salammoniac ..	.. £32 per ton d/d.
Salt Cake.. ..	.. £3 10s. per ton d/d.
Soda Caustic, solid	.. Spot lots: delivered. £16 17s. 6d. to £19 7s. 6d. per ton, according to strength. 20s. less for contracts.
Soda Crystals ..	.. £5 5s.—£5 10s. per ton ex railway depots or ports.
Sod. Acetate 97/98%	.. £24 per ton.
Sod. Bicarbonate	.. £10 10s. per ton, carr. paid.
Sod. Bichromate..	.. 4¼d. per lb.
Sod. Bisulphite Powder 60/62%.. ..	.. £17—£18 per ton, according to quantity, f.o.b., 1-cwt. iron drums included.
Sod. Chlorate ..	.. 3d. per lb.
Sod. Nitrate refd. 96%	.. £13 5s.—£13 10s. per ton ex Liverpool. Nominal.
Sod. Sulphide conc. 60/65	About £14 10s. per ton d/d.
Sod. Sulphide cryst.	.. £9 per ton d/d.
Sod Sulphite, Pea Cryst.	£15 per ton f.o.r. London, 1-cwt. kegs included.

RUBBER CHEMICALS

Antimony sulphide—	
Golden	.. 6½d.—1s. 2d. per lb., according to quality.

example, one of the most recent applications is its addition to copper for electric transmission wires. Copper wire containing 1 per cent. of cadmium has a higher tensile strength, is harder and more resistant to wear than hard-drawn copper wire and, further, the conductivity is not appreciably impaired. The superiority of this alloy has been proved, particularly in connexion with electrical trolley wires.

WILLIAM G. WAGNER

THE KINETIC THEORY OF GASES. By Prof. E. BLOCH. Translated by P. A. SMITH. Pp. xiv + 178. London: Methuen and Co., Ltd. Price 7s. net.

The translation of Prof. Bloch's stimulating booklet, the French original of which appeared in 1921, affords to English readers not only an account of the classical kinetic theory, but also of those recent developments which have made the kinetic theory one of the most vital branches of modern theoretical physics.

The first four chapters deal with the classical theory in the form associated with the names of Maxwell and Clausius, and a clear outline account is given of the more important considerations which are characteristic of this stage of the development of the theory. In Chapter 5 the methods of statistical mechanics and the theoretical developments which we owe to Boltzmann are briefly considered, and in Chapter 6 the reader is introduced to the theory of quanta and to those modern views on energy exchange which are associated in particular with the theories of Planck and Einstein.

The remaining four chapters are devoted to the consideration of Brownian motion, fluctuations, rarefied gases, the width of spectral lines and molecular constants. Undoubtedly this is the most interesting part of the book, and the various directions in which modern research has served to amplify the fundamental notions underlying the kinetic theory are clearly expounded. All purely mathematical developments are avoided, the object of the author being to present fundamental ideas in logical sequence, and to show that the kinetic theory is built upon foundations which are almost unassailable.

In some few instances, statements are made which in form or substance are at least questionable. For instance, on p. 63, in a discussion of the distribution of a mixture of gases under the influence of gravity, it is said that "each of the gases distributes itself in height under the influence of gravity as if it were alone, *the law of distribution varying more rapidly* the greater the molecular weight of the gas." Again, on p. 80, there is an argument relative to the heat capacities of gases and the equipartition theory which would not meet with general acceptance. Such minor blemishes do not however suffice to depreciate sensibly the intrinsic value of the book, which can be warmly recommended to all students of physical chemistry.

Phenacetin ..	.. 5s. 6d. per lb.
Phenazone ..	.. 6s. 10d. per lb.
Phenolphthalein ..	.. 5s. 6d. per lb. for cwt. lots. Supply exceeds demand.
Potass. Bitartrate— 99/100% (Cream of Tartar) ..	.. 84s. per cwt., less 2½% for ton lots.
Potass. Citrate ..	.. 1s. 10d.—2s. 2d. per lb.
Potass. Ferricyanide	.. 1s. 9d. per lb. Quiet.
Potass. Iodide ..	.. 16s. 8d.—17s. 5d. per lb., according to quantity. Steady market.
Potass. Metabisulphite	.. 7½d. per lb., 1-cwt. kegs included. F.o.r. London.
Potass. Permanganate	.. 7¼d. per lb. spot. Forward prices higher.
Quinine Sulphate	.. 2s. 3d.—2s. 4d. per oz., in 100 oz. tins. Steady market.
Resorcin	.. 5s. 3d. per lb.
Saccharin ..	.. 63s. per lb., in 50-lb. lots.
Salol	.. 3s. 6d. per lb. for cwt. lots. Slightly lower. Limited demand.
Silver Proteinate..	.. 9s. per lb. for satisfactory product, light in colour.
Sod. Benzoate, B.P.	.. 2s. 6d. per lb. Supplies of good quality now available.
Sod. Citrate, B.P.C., 1923	1s. 11d.—2s. 2d. per lb., according to quantity.
Sod. Hyposulphite— Photographic ..	.. £13—£15 per ton, according to quantity, d/d. consignee's station in 1-cwt. kegs.
Sod. Metabisulphite cryst.	37s. 6d.—60s. per cwt. nett cash, according to quantity.

Sod. Nitroprusside	16s. per lb.
Sod. Potass. Tartrate (Rochelle Salt)	75s.—82s. 6d. per cwt., according to quantity. Quiet market.
Sod. Salicylate	Fair demand. Powder 2s. 1d.—2s. 3d. per lb. Crystal at 2s. 2d.—2s. 4d. per lb. Flake 2s. 6d. per lb. Good demand. Market firmer.
Sod. Sulphide—	
Pure recryst.	10d.—1s. 2d. per lb.
Sod. Sulphite, anhydrous	£27 10s. per ton, minimum 5-ton lots, increasing according to quantity, 1-cwt. kegs included.
Sulphonal	14s. 6d. per lb. Little demand.
Thymol	18s. per lb. Firmer market.

PERFUMERY CHEMICALS

Acetophenone	11s. 3d.	per lb.	
Aubepine	13s. 6d.	„	Again cheaper.
Amyl Acetate	3s.	„	
Amyl Butyrate	6s. 6d.	„	
Amyl Salicylate	3s. 3d.	„	
Anethol (M.P. 21/22° C.)	4s. 6d.	„	
Benzyl Acetate from Chlorine-free Benzyl Alcohol	2s. 9d.	„	
Benzyl Alcohol free from Chlorine	3s. 3d.	„	Cheaper.
Benzaldehyde free from Chlorine	3s. 3d.	„	Cheaper
Benzyl Benzoate	3s. 6d.	„	
Cinnamic Aldehyde—			
Natural	18s. 6d.	„	
Coumarin	18s. 3d.	„	Cheaper.
Citronellol	18s.	„	Dearer.
Citral	8s.	„	
Ethyl Cinnamate	12s. 6d.	„	
Ethyl Phthalate	3s.	„	
Eugenol	10s. 6d.	„	
Geraniol (Palmarosa)	33s. 6d.	„	
Geraniol	12s. 6d.—20s. per lb.		
Heliotropine	6s. 9d.	per lb.	
Iso Eugenol	16s.	„	
Linalol ex Bois de Rose	26s.	„	
Linalyl Acetate	26s.	„	
Methyl Anthranilate	10s.	„	
Methyl Benzoate	5s.	„	
Musk Ambrette	50s.	„	
Musk Xylol	14s.	„	
Nerolin	4s. 6d.	„	
Phenyl Ethyl Acetate	15s. 6d.	„	
Phenyl Ethyl Alcohol	16s.	„	
Rhodinol	52s. 6d.	„	Cheaper.
Safrol	1s. 10d.	„	
Terpineol	2s. 4d.	„	
Vanillin	25s. 6d.	„	

ESSENTIAL OILS

Almond Oil, Foreign S.P.A.	15s. 6d. per lb.
Anise Oil	2s. 10d. per lb.
Bergamot Oil	15s. 6d. per lb. Cheaper.
Bourbon Geranium Oil	32s. per lb. Cheaper.
Camphor Oil	65s. per cwt
Cananga Oil Java	11s. 3d. per lb. Dearer.
Cassia Oil, 80/85%	9s. 9d. per lb.
Cinnamon Oil, Leaf	6½d. per oz.
Citronella Oil—	
Java 85/90%	7s. per lb. Dearer.
Ceylon	3s. 5d. per lb. Cheaper.
Clove Oil	8s. 3d. per lb.
Eucalyptus Oil 70/75%	2s. 2s. per lb. Cheaper.
Lavender Oil—	
French 38/40% Esters	35s. per lb.
Lemon Oil	3s. 2d. per lb.
Lemongrass Oil	5s. 9d. per lb. Dearer.
Orange Oil, Sweet	11s. per lb.
Otto of Rose Oil—	
Bulgarian	42s. 6d. per oz. Dearer.
Anatolian	28s. per oz. Dearer.
Palma Rosa Oil	17s. per lb. Dearer.
Peppermint Oil—	
Wayne County	43s. 6d. per lb. nominal.
Japanese	22s. 6d. per lb. nominal.
Petitgrain Oil	9s. 9d. per lb.
Sandal Wood Oil—	
Mysore	26s. 7d. per lb.
Australian	18s. 6d. per lb.

PATENT LIST

The dates given in this list are, in the case of Applications for Patents those of applications, and in the case of Complete Specifications accepted those of the Official Journals in which the acceptance is announced. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition before Jan. 26th; they are on sale at 1s. each at the Patent Office, Sale Branch, Quality Court, Chancery Lane, London, W.C. 2, on Dec. 11th.

I.—Applications

Best. Emulsifying or mixing apparatus 27,429. Nov. 17.

Blumenfeld and Weizmann. Filtration of solutions etc. 27,928. Nov. 21.

Courtaulds, Ltd., and Lungo. Filters. 27,830. Nov. 20.

Crozemarie and Malvos. Furnaces. 27,726. Nov. 19.

Jenaer Glaswerk Schott and Gen. Filters. 28,016. Nov. 22. (Ger., 11.12.23.)

Kirkup and Thompson. Rotary screen and dryer. 27,874, 27,875. Nov. 21.

Lamplough. Drying and mixing granular etc. materials. 27,669. Nov. 19.

Metropolitan-Vickers Electrical Co., Ltd. Deoxidiser 28,002. Nov. 22. (U.S., 21.12.23.)

Metropolitan-Vickers Electrical Co., Ltd. Deoxidisation of gases. 28,003. Nov. 22. (U.S., 29.12.23.)

Nathorst. Roller grinding mills. 28,030. Nov. 22. (Sweden, 24.11.23.)

Oughtibridge Silica Firebrick Co., Ltd., and Brooke. Kilns. 27,723. Nov. 19.

Owen. Drying. 27,916. Nov. 21.

Surtees. Centrifugal machines for emulsifying, mixing, or grinding. 27,620. Nov. 19.

Thomassen. Centrifugal separators. 27,483. Nov. 17. (Ger., 27.5.24.)

I.—Complete Specifications Accepted

17,891 (1923). Cutler. Drying-kilns. (224,575.)

20,866 (1923). Aluminium Plant and Vessel Co., Ltd., and Gough. Mixing and agitating machines. (224,607.)

20,934 (1923). Lucas. Gas-fired oven furnaces. (224,610.)

23,396 (1923). Borner. Treatment of granulated, pulverulent, and the like materials. (224,652.)

30,540 (1923). Risberg. Centrifugal liquid separators. (224,734.)

7734 (1924). Dupuy. Apparatus for distilling solids or liquids. (213,586.)

9446 (1924). Jones. Separation of substances having different density. (224,806.)

10,972 (1924). Patentaktiebolaget Grondalramen. Rotary or like furnaces. (215,745.)

12,277 (1924). Karpinsky and Anderson. Installation for the separation of liquids. (217,197.)

II.—Applications

Auld and Dunstan. Treatment of hydrocarbons. 27,956. Nov 21

Barrett Co. Manufacture of polymerised naphthas. 27,612 Nov. 18. (U.S., 23.11.23.)

Birkner, Otte, Walther u. Co. Combustion of watery, woody, and bituminous fuels. 27,951. Nov. 21. (Ger., 9.12.23.)

Chomó and Defossez. Coke ovens. 27,487. Nov. 17.
Helps. Gas manufacture. 27,373. Nov. 17.
Metropolitan-Vickers Electrical Co., Ltd. 28,003. *See* I.
Rude. Gasifying oil in water-gas production etc. 27,894. Nov. 21.
Suida. Process for obtaining gases rich in ethylene. 28,027. Nov. 22. (Austria, 30.11.23.)
Terrell. Manufacture of incandescent gas mantles. 27,953. Nov. 21.
Trent. Manufacture of fuel. 27,457. Nov. 17. (U.S., 9.2.24.)

II.—Complete Specifications Accepted

13,033 and 31,983 (1923). Salerni and Salerni. Distillation or treatment of carbonaceous and other materials. (224,568.)
20,298 (1923). Ricard, Allenet et Cie. Conversion of gaseous aliphatic ethylene hydrocarbons into liquid hydrocarbons. (202,311.)
26,015 (1923). Chadwick. Separating gasolene from natural gas or hydrocarbon vapours. (224,688.)
7734 (1924). Dupuy. *See* I.

III.—Application

Barrett Co. 27,612. *See* II.

IV.—Application

Soc. of Chemical Industry in Basle. Manufacture of indigoid dyestuffs. 28,017. Nov. 22. (Switz., 30.11.23.)

V.—Applications

Courtaulds, Ltd., and Lungo. Apparatus for manufacture of artificial silk. 27,828, 27,829. Nov. 20.
Ferdinando and Griffiths. Apparatus for manufacture of artificial silk. 27,607, 27,608 and 27,670. Nov. 18 and 19.
Granton. Washing cellulose etc. 27,999. Nov. 22.
Kuhn, Le Breton, and Schaeffer. 27,846. *See* XIX.
Lilienfeld. Manufacture of cellulose compounds. 27,837. Nov. 20. (Austria, 10.10.24.)
Rogers (Präcisionsgussfabrik Geb. Eckert). Melting celluloid masses. 27,478. Nov. 17.

V.—Complete Specifications Accepted

17,765 (1923). Lilienfeld. Process of preparing alkali celluloses and cellulose ethers. (200,816.)
18,091 (1923). Lilienfeld. Process of preparing low-water-content alkali cellulose and cellulose ethers. (200,827.)
20,212 (1923). Cellon-Werke, Eichengrun. Production of thin films of cellulose derivatives. (202,306.)
25,348 (1923). British Celanese, Ltd., Ellis, Stevenson, and Croft. *See* VI.
26,329 (1924). Cellon-Werke, Eichengrun. Production of thin films of cellulose derivatives. (224,848.)

VI.—Applications

Akt.-Ges. für Anilin-Fabrikation. Process for dyeing furs etc. 28,018. Nov. 22. (Ger., 23.1.24.)
Baddiley, and British Dyestuffs Corp., Ltd., and Browning. Dyeing acetyl cellulose. 28,013. Nov. 22.
Jackson (Fuld and Hatch Knitting Co.). Yarn-dyeing tanks. 27,484. Nov. 17.
Sandoz Chemical Co., Ltd. Dyeing cotton materials. 27,545. Nov. 17.

VI.—Complete Specifications Accepted

25,348 (1923). British Celanese, Ltd., Ellis, Stevenson, and Croft. Dyeing, printing or stencilling of cellulose acetate. (224,681.)
25,412 (1923). Brandwood and Brandwood. Apparatus for the dyeing or other fluid-treatment of yarn packages on spindles. (224,683.)
32,591 and 32,605 (1923). Jackson (Flint-kote Co.). Manufacture of saturated or impregnated fibrous material (224,751 and 224,752.)
23,101 (1924). Standard Silk Dyeing Co. Washable dyed silk piece goods, and process of dyeing same. (222,520.)

VII.—Applications

Atlantic Chemical Co., Ltd., and Fleming. Manufacture of concentrated borate from crude borate of lime. 28,021, 28,022. Nov. 22.
Bailey. Production of helium from radio-active ores etc. 27,616. Nov. 19.
Farbwerke vorm. Meister, Lucius, und Brüning. Feeding salt-cake furnace. 28,019. Nov. 22. (Ger., 26.11.23.)
Naamlooze Vennootschap Philips' Gloeilampenfabrieken. Process of separating a mixture of hafnium and zirconium compounds. 27,836. Nov. 20. (Holland, 12.12.23.)
Packards and J. Fison (Thetford), Ltd., and Mills. Chambers for manufacture of sulphuric acid. 27,449, 27,450. Nov. 17.
Soc. Chimique des Usines du Rhône. Manufacture of arsenates of the alkaline-earth metals. 27,566. Nov. 18. (Fr., 3.1.24.)

VII.—Complete Specifications Accepted

25,936 (1923). L'Oxhydrique Française. Manufacture of hydrogen. (206,822.)
26,526 (1923). Henshaw, Stonier, and Talk O' th' Hill Colliery, Ltd. Production of dry neutral sulphate of ammonia. (224,697.)
2581 (1924). Soc. Chimique des Usines du Rhône. Manufacture of the arsenates of the alkaline-earth metals. (216,098.)
3230 (1924). Soc. Chimique des Usines du Rhône. Manufacture of calcium arsenate. (214,951.)
11,846 (1924). Schmidt and Ges. für Chemische Produktion. Obtaining hydrochloric acid free from arsenic. (216,129.)

VIII.—Applications

Manufacture des Glaces et Produits Chimiques de St. Gobain, Chauny, et Cirey. Continuous furnace for glass manufacture. 27,436. Nov. 17. (Fr., 6.12.23.)
Tams. Semi-porcelain body for pottery. 27,972. Nov. 22.

VIII.—Complete Specification Accepted

21,327 (1923). Shaw. Furnaces for melting and refining glass etc. (224,622.)

IX.—Applications

Eckel. Process of making cement and iron. 27,485. Nov. 17.
Hemming. Material for roads etc. 27,446. Nov. 17.
Wade (Soc. Anon. Italiana per la Produzione di Calci é Cementi di Segni). Manufacture of hydraulic cement. 27,431. Nov. 17.

X.—Applications

Apold and Fleissner. Treatment of ores etc. 27,577. Nov. 18.
Brunskill. Preventing surface corrosion in aluminium alloys. 27,619. Nov. 19.
Eckel. 27,485. *See* IX.
Grunder and Maas. Composition for treating hot metals. 27,721. Nov. 19.
Hernandez, de. Apparatus for distillation of ores. 27,710. Nov. 19.
Prentice. Method of heat-treating oxides, ores, etc. 27,759. Nov. 20.
Swingler and Wilson. Aluminium alloy. 27,790. Nov. 20.
Wade (International Nickel Co.). Manufacture of alloys. 27,917. Nov. 21.

X.—Complete Specifications Accepted

18,228 (1923) and 9279 (1924). Scrivon and Guise. Treatment of metal articles to prevent tarnish. (224,579.)
22,135 (1923). British Thomson-Houston Co., Ltd. (General Electric Co.). Composite metals. (224,639.)
32,416 (1923). Clerc and Nihoul. Treatment of complex ores containing zinc. (209,100.)
13,939 (1924). Chemische Fabrik Griesheim-Elektron and Beielstein. Recovery of light metals from scrap. (219,287.)
17,612 (1924). Western Electric Co., Ltd. (Western Electric Co., Inc.). Metallic composition. (224,836.)

XI—Applications

British Thomson-Houston Co., Ltd. Electron-emitting electrodes. 27,549. Nov 18. (U.S., 18.12.23.)

Kirkaldy. Electrodes. 27,787. Nov. 20. (U.S., 20.11.23.)

Willment. Electric battery. 27,899. Nov. 21

XII.—Applications

Bollmann. Decolorising ... etc. 27,842 Nov. 20. (Ger., 24.3.24.)

British Glues and Chemicals, Ltd., ... Drew. Extraction of fat from bones. 27,714. Nov. ...

Falck. Production of soaps. 27,... Nov. 17.

Riedel Akt.-Ges. Fat-splitting ag... Nov. 17. (Ger., 5.1.24.)

Wade (Divine). Manufacture of soap. ...

XIII.—Application

British Cyanide... Ltd., and Rossiter ... artificial resins. ... Nov. 22.

XIII.—Complete Sp... Accepted

26,093 (1923). P... Insulating fire-resisting water-paint. (224,700.)

XIV.—Complete Spec... Accepted

27,465 (1923). A... Rubber Co., Ltd. Direct production of rubber she... (223,189.)

XVI.—Application

Cowles. Production ... fertilisers. 27,947. Nov. 21.

XVII.—Application

Philipp. Manufacture of sugar. 27,736. Nov. 20 (Ger., 24.11.23.)

XVIII.—Application

Barbet. 27,473. *See* XX.

XVIII.—Co... Specifications Accepted

20,579 (1923). Horst, von. Production of hop extracts. (224,594.)

1795 (1924). Ricard, Allenet et Cie. *See* XX.

XIX.—Applications

Hitchcock. Manufacture of wholemeal. 27,741. Nov. 20.

Kahn, Le Breton, and Schaeffer. Transforming lower vegetables into useful products. 27,846. Nov. 20. (Fr., 20.11.23.)

XIX.—Complete Specification Accepted

23,838 (1923). Hilditch, Wheaton, and Crosfield and Sons, Ltd. Purifying or softening of water by means of base-exchanging compounds, and regeneration of such compounds when spent. (224,656.)

XX.—Applications

Barbet. Production of alcohol. 27,473. Nov. 17. (Fr., 17.11.23.)

Blagden, and Howards and Sons. Manufacture of thymol. 27,707. Nov 19

Soc. Chimiques des Usines du Rhône. Process for manufacture of malonic-acid esters. 27,567. Nov. 18. (Fr., 7.2.24.)

Timmer and Vogl. Medical compound. 28,014. Nov. 22. (Austria, 23.11.23.)

XX.—Complete Specifications Accepted

20,298 (1923). Ricard, Allenet et Cie. *See* II.

1764 (1924). Ellis (Soc. Chimique des Usines du Rhône). Preparation of salts of the p-oxyomacylamino-phenol-arsinic acids. (224,764.)

1795 (1924). Ricard, Allenet et Cie. Process of dehydrating alcohol. (210,761.)

11,327 (1924). Soc. of Chemical Industry in Basle. Use of medicaments insoluble or sparingly soluble in water. (218,982.)

XXI.—Applications

Dawson. Colour photography. 27,807. Nov. 20.

Haling. Emulsion for repairing kinematograph films. 27,391. Nov. 17.

GENERAL NOTES

Official Trade Intelligence

The Department of Overseas Trade (Development and Intelligence, 35, Old Queen Street, London, S.W. 1) has received the following enquiries for British goods. British firms may obtain further information by applying to the Department and quoting the specific reference number :—*Australia :* Iron, steel, (529); Artificial silk, (412/7/1/1/296); *Brazil :* Tinplate, iron, steel, copper, brass, cement, (554); *British India :* Paper, iron (Director-General, India Store Department, Branch No. 10, Belvedere Road, Lambeth, S.E. 1); *China :* Chemicals, ...urgical and scientific instruments, (547); *Egypt :* ...os, (543); Varnish, chemicals, (545); *Sweden :* ... wire, sulphur, limestone, steel, lead, rubber, ... *Tunis :* Artificial silk, oil, (546). *Canada :* Paper ... Leather (B.X./1377); *China :* Artificial ...); *Egypt :* Chemicals, glassware (B.X./13...) ...*ary :* Soap, perfumery (568); *Norway :* C... (569); *Portugal :* Creosote (570); *Swed...* Rubber (572).

Notes on Plant an. Products

The Thermal Syndicate, Ltd., of Neptune Bank, Wallsend-on-Tyne, has sent a copy of the latest illustrated list of Vitreosil laboratory ware and apparatus, including the transparent variety of Vitreosil made from fused quartz. The list reveals the rapid advances made in the manufacture and applications of Vitreosil. the latest product being a mercury condensation pump made of pure fused quartz. The pump is compact in design (length 25 cm., diameter 3·3 cm., gas inlet 1·5 cm.), water cooled and works at about 200 c.c. per second. With a backing pump giving a vacuum of 0·2 mm., a vacuum of 0·000002 mm. may be readily and quickly obtained. A liquid air trap is required to remove the last traces of mercury vapour. The pump, which is silent in operation, can be heated electrically or by gas and will work effectively with only 5 c.c. of mercury. Such a piece of apparatus has long been wanted in the laboratory, and its high efficiency, ease of operation and reasonable price (without mercury, £5 2s. 6d.; with mercury seal and silica to ground glass joints £6 12s. 6d.). make it of interest to all who have to work with high vacua. The list and prices describe laboratory and other ware in transparent, translucent and opaque Vitreosil, and includes a useful bibliography relating to silica ware that alone should tempt chemists to send for a copy.

PUBLICATIONS RECEIVED

Elements of Colloidal Chemistry. By H. Freundlich. Translated by G. Barger, F.R.S. Pp. vii + 210. London: Methuen and Co., Ltd., 1924. Price 7s. 6d.

Scientific Research and Human Welfare. By F. S. Harris, with the collaboration of N. I. Butt... Pp. ... + 406. London and New York: MacMillan Co., Ltd., 1924. Price 12s.

Sulphuric Acid Concentration. Vol. II. In Heated Vessels. By P. Parrish and F. C. Snelling. Pp. xi + 147. London: E. Benn, Ltd., 1924. Price 6s.

JOURNAL *of* THE SOCIETY OF CHEMICAL INDUSTRY.

CHEMISTRY & INDUSTRY

Official Organ of the Federal Council of Pure and Applied Chemistry

which consists of Representatives from

The Chemical Society, the Society of Chemical Industry, the Association of British Chemical Manufacturers, the Institute of Chemistry, the Society of Public Analysts, the Faraday Society, the Institute of Brewing, the Society of Dyers and Colourists, the Society of Glass Technology, the Iron and Steel Institute, the Ceramic Society, the Institution of Gas Engineers, the Society of Leather Trade Chemists, the Royal Photographic Society, the Mineralogical Society, the Biochemical Society, the Institute of Metals and the Royal Agricultural Society.

VOL. 43 NEW SERIES | LONDON, DECEMBER 12, 1924 | NO. 50

EDITORIAL

THERE is a limit to the amount of work a man can do; the limit varies greatly, and the busy man learns by experience how to economise his time and his energy: he learns how to cast on to others the routine work which they can do better than he can and how to concentrate his own energies so as to bring into action those qualities of judgment, of intuition or of persuasion which cause the busy man to be busy. The limit nevertheless exists, and Sir William Alexander finds that the attention he chooses to give to his own business and the attention he chooses to give to Parliament do not leave him a sufficient margin to deal with so important a task as the chairmanship of the British Dyestuffs Corporation. He has therefore resigned this office. Sir William Alexander has impressed everyone by his business ability; he has had a singularly difficult task, and the current opinion is that he has done well; in his retirement he will treasure the goodwill and the gratitude of the many shareholders whose fortunes he has gradually steered into smoother water, though not quite into that haven which denotes leisure and comfort. He is succeeded in the chairmanship by Lord Ashfield, who is well acquainted with the affairs of the Corporation, having been on the board for several years, and is a business man with singular energy and powers of organisation. The Government in the place vacated by Lord Ashfield, as a Government director, has appointed Sir Alfred Mond. Sir Alfred Mond has not quite reached his limit; he is known to our readers as a successful man of business, a capable chemical manufacturer, and a statesman. He is reputed to have sufficient shrewdness in business to enable him to earn an income of no mean size; he does not waste time, but gets to the root of the matter at once; he was a clever politician when he entered the House of Commons, and his appearance speedily obtained for him that prize so much coveted by the politician, a caricature in *Punch*. For a short time his political opponents scoffed, but only for a short time. He talked good sense; he has, and from the early days had, a political *flair*; he learned the atmosphere of the House, and all varieties of men there quickly learned to respect him for his sound judgment and convincing power of speech. He developed from the clever politician into the weighty statesman very speedily, and is now the rising hope of that small band of stern and unbending Liberals who have survived the flood.

* * *

It is not, however, Sir Alfred Mond's eminence in politics which is significant. He has all his life been connected with the chemical industry. In textbooks it is convenient, and in Acts of Parliament it is necessary, to draw an exact and arbitrary line between organic and inorganic chemistry. It is unnecessary and impossible to divide the chemical industry in this manner. Our chemical industry is bound together by links and by interests as innumerable as the stars that shine. It is, we think, essential that our heavy chemical industry, our fine chemical and our dyestuffs industry shall have far greater community of interest, of ambition, of purpose. We welcome the fact that one of the leaders in our successful heavy chemical industry should join the board of our leading dyestuffs company. We sincerely trust

that this policy will be continued and that those who have proved their ability to guide firms engaged in the manufacture of chemicals will be given the opportunity of helping those interested in the newer and less sturdy branches of the industry. We notice that Lord Colwyn has also been invited to join the Board; his great experience in important undertakings makes him a director of exceptional value. His wise counsel will be a great asset to the Dyestuffs Corporation. The next time that a vacancy occurs on the Board we think someone with chemical experience, having an acquaintance with chemists and their ways and with the broad outlines of chemical research and chemical development, should prove also of great value. We learn that in the treaty with Germany it is agreed that the importation of dyestuffs into this country will continue to be subject to the licensing restrictions now in force. We scrupulously avoid any reference to political topics in these columns; but for this reservation we should have indicated at some length our belief that the chemical industry of this country is so bound together that no one branch of it can become weak or even threatened without doing incalculable harm to the other branches, and to the science which is the foundation of the whole industry.

* * *

The electrolytic decomposition of salts enabled Davy in the year 1807 to make the important discovery of the metals potassium and sodium, but the nature of electrolysis was imperfectly understood until the classical work of Faraday was published ninety years ago. It was in 1840 that Messrs. Wright and Parkes made electro-plating in silver a commercial success. Nickel-plating became commercially possible about the year 1870. The paper we publish this week by Prof. A. J. Hale shows how interesting and useful this method of preparing elements has become. Prof. Hale is the author of one of our standard books on the subject, and the detailed account we publish of the various types of cells and processes in use to-day is full of valuable information. The preparation of metals and their purification is merely one application of electrolysis; the coating of one metal with a veneer of a different metal is merely another application; the production of gases merely a third. The methods described by Prof. Hale are examples of a great principle of enormous importance. How much this principle will be developed during the next fifty years no one can say! The cheap electric power available in Norway, Switzerland, Italy, America, and some other countries makes many industries possible which would otherwise be too expensive. It was cheap water-power, we have always understood, rather than cheap coal which first established our textile industries in Lancashire and the West Riding of Yorkshire. The time may come again when the most favoured parts of the world will be places whose hills and mountains yield an annual rainfall of fifty or sixty inches a year. Shall we some time in the future have local sections of the Society whose habitations and names suggest the Himalayas, the Caucasus or the Ural Mountains?

MODERN ELECTROLYTIC CELLS

By Professor A. J. HALE

The cells in use at the present time for producing metals or chemicals by electrolysis may be conveniently divided into three groups according as they are employed for: (*a*) The winning or refining of metals; (*b*) the production of industrial gases; or (*c*) the production of various inorganic and organic compounds.

WINNING AND REFINING OF METALS

In this group are the simplest and, at the same time, some of the most complicated designs, as may be realised by considering, on the one hand, the ordinary type of vat used for copper refining and, on the other hand, such cells as are used for winning metals from fused chlorides or even the cell employed

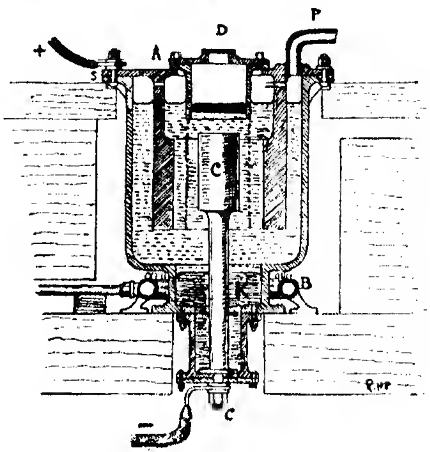

Fig. 1
Castner Sodium Cell

in the Castner process for obtaining metallic sodium. The rectangular vats used for refining copper and lead, and for the electrolytic extraction of copper and zinc are usually constructed of wood and lined with lead. They may be 30 ft. long, 4 ft. wide, and 5 ft. deep, the sheet cathodes and anodes being suspended alternately from bus bars, which cross the width of the tank and, resting on the top of the sides, make contact with their appropriate positive or negative leads. No covering is required and the process, which is akin to electro-plating, is of a simple and well-known type.

Enormous quantities of high-grade copper are refined in this manner, and the process is now in extensive use for dealing with copper and zinc solutions obtained by the extraction of low-grade ores. Similar vats, but smaller, are employed for refining lead, tin, nickel, iron, silver and gold but, occasionally, diaphragms, moving electrodes or scraping devices render the construction less simple than usual.

The cells used for obtaining aluminium, sodium, magnesium and calcium are of different design from those just considered because the electrolysis of a fused salt or compound at temperatures ranging from 300° up to 1000° C. necessitates what may be

termed an electrolytic furnace. The ordinary graphite tank, supported externally by an iron frame, in which aluminium is obtained from a molten mixture of alumina and cryolite will be familiar to all students of electrochemistry. This cell was first employed in 1885, and the cell, introduced a few years later by Castner, for preparing metallic sodium from fused caustic soda (Fig. 1) is almost as well-known. Experience gained from these two cells has enabled later workers to devise suitable electrolysers for dealing with the molten chlorides or fluorides of magnesium, sodium, calcium, lead and zinc.

Aluminium is sufficiently dense to sink to the bottom of the cell from which it can be tapped at intervals, but sodium, calcium and magnesium are less dense than the electrolyte of fused chlorides employed in obtaining them, and the metals must therefore be collected at the top of the cell in some similar manner as that used in the Castner sodium cell

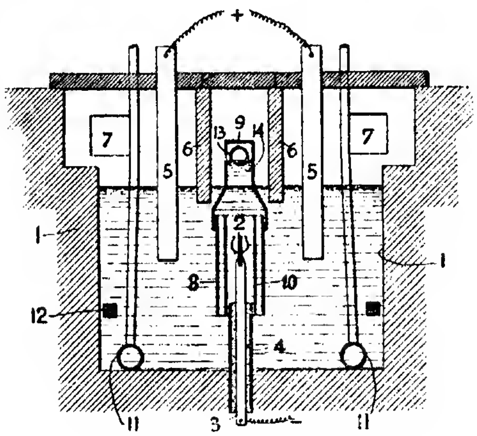

Fig. 2

Sodium Cell of the Society of Chemical Industry in Basle

in which the metal collects on the fused caustic soda beneath the cover, in an atmosphere of hydrogen

One of the earliest cells to be used successfully with fused sodium chloride was that of the Society of Chemical Industry in Basle (Fig. 2). The furnace is of rectangular cross section, and built of fire-brick, in which are helical coils, 11, for heating and melting the charge by suitable alternating current, and electrodes, 12, for the same purpose, whilst outlets, 7, for chlorine discharged from the graphite anodes, 5, are provided in the outer compartments of the cell, which is divided in two parts by diaphragms, 6, attached to the cover and further diaphragms, 8, attached to the bell, 9, in which the sodium, 14, collects prior to overflowing through pipe, 13, to a receiving vessel. The metal cathode, 2, is encased in a sleeve, 4, which also carries the negative lead, 3, tightly wedged in the sleeve by a packing of magnesite, and one or more wire nets, 10, are fixed between the cathode and the diaphragm 8, in order to prevent any sodium from passing into the anode compartments.

Difficulty has been experienced in preventing volatilisation of sodium at the temperature of molten salt (850° C.), and the process of McNitt (1916) is

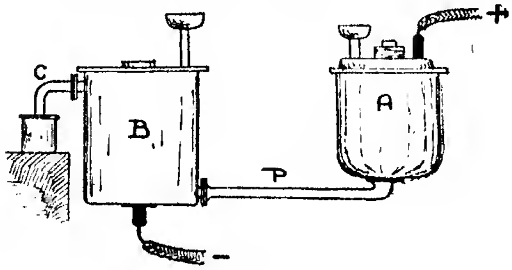

Fig. 3

Ashcroft Cell for Metallic Sodium

carried out in a cell resembling that of Castner in most respects, but a pressure of 900 millimetres is maintained within the cell, so that the boiling point of the sodium is raised by about 100° C. A side tube is provided for the metal to overflow into a suitable receiver (U.S.P. 1,197,137/16). Subsequently, McNitt attempted to overcome the difficulty due to the volatilisation of sodium by using an electrolyte composed of sodium chloride 36 parts, and sodium carbonate 64 parts, the mixture having a melting point of 600° (U.S.P. 1,219,808/17).

Ashcroft, in his earlier cell for electrolysing fused salt, adopted the twin-cell principle (Fig. 3) with a movable electrode of molten lead. In compartment, A, chlorine is liberated on graphite anodes and sodium discharged into the lead; the alloy is then impelled to compartment, B, containing fused soda, where it becomes the anode and the sodium, passing to the iron cathode, overflows by a side pipe, C, to a receiver.

This principle has been adopted in modern cells for obtaining magnesium. For example, the Mag-

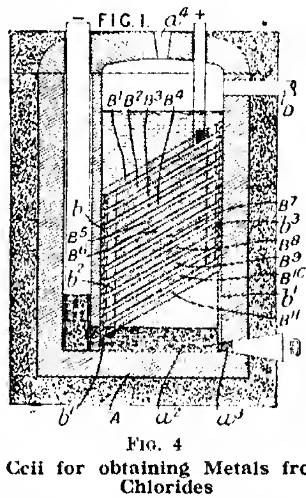

Fig. 4

Ashcroft Cell for obtaining Metals from Fused Chlorides

nesium Company in their works at Wolverhampton (S. T. Allen, *Electrician*, 1922, 88, 92) employ two connected cells containing fused magnesium

chloride and a movable molten lead-magnesium electrode. Each unit takes 5000 ampères at 5 volts and liberates 100 lb. of magnesium from the fused chloride per 24 hours, with an energy expenditure of 8·5 kw.-hrs. per pound of metal.

This cell is modelled on similar lines to that of Ashcroft (E.P. 152,879/19) in which molten lead acts as a carrier of the magnesium which is deposited from the fused salt in the anode compartment containing the graphite electrodes. The alloy is allowed to overflow into the cathode cell which is fitted with iron electrodes; here the magnesium is discharged and rises to the surface of the electrolyte, where it may be collected.

A further cell, suitable more particularly for obtaining zinc and lead from their fused chlorides (E.P. 198,024/22), is shown in Fig. 4. A series of closely spaced inclined graphite electrodes, B_1—B_{11}, is immersed in the electrolyte contained in a tank

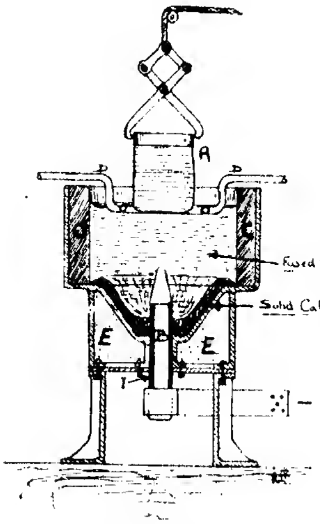

Fig. 5
Cell for Obtaining Metallic Calcium

of refractory material. The first and last electrodes only act as terminals and the rest are bi-polar, positive on the upper surfaces on which metal will be discharged and negative on the under surface on which chlorine is discharged. Holes, b^2, near the lower ends of the electrodes, allow metal to run down to the reservoir, a^2, and the holes, b^3, near the upper ends, allow chlorine to pass away to the collecting chamber.

Carrier's cell for electrolysing fused salt (U.S.P. 830,051/1906) was constructed on the twin-cell principle, the molten alloy of lead and sodium being allowed to overflow from the anode to the cathode compartment in which the sodium was discharged.

Cells used for obtaining magnesium from the fused chlorides are sometimes based upon the design used by Seward and von Kügelgen in their cell for calcium (Fig. 5), in which the iron cathode is fixed to the bottom of the tank, whilst the calcium rising to the

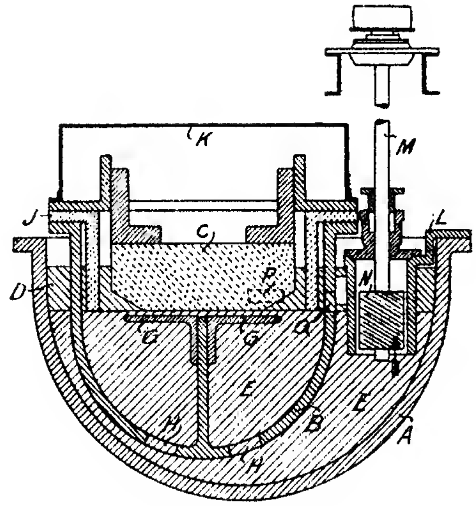

Fig. 6
Mathesius Cell

water-cooled region of the electrolyte is removed, as indicated in the diagram.

In a later cell of the Westinghouse Electric Company (U.S.P. 1,396,919/20), the cathode is supported centrally, so that it dips into the fused chloride and is moved continuously upwards, carrying with it the adherent stick of metallic calcium formed by a circular water-cooling arrangement round the cathode. The bottom of the tank is water-cooled and anodes

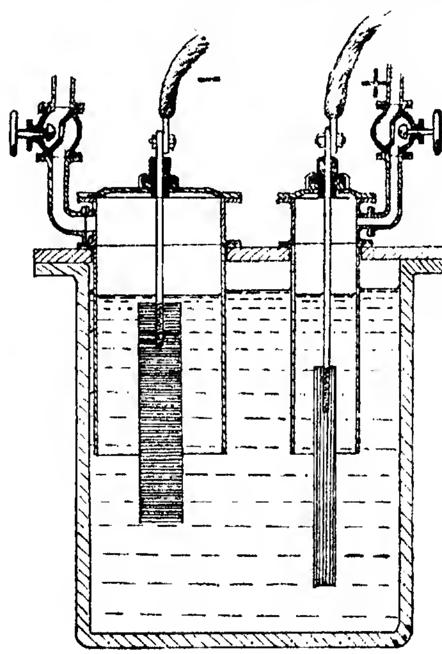

Fig. 7
Jaubert Cell

of graphite are arranged round the cathode external to the water-cooling pipe.

Later, G. O. Seward and the American Magnesium Company brought out a cell in which the cathode is fixed in the bottom of the cell, and the molten metal
